The system introduced in this book, no doubt owing to the excellent results obtained by its use, was rapidly recognised as the standard method of teaching analysis in most of the institutions existing at that time. Soon the course began to be further developed, book after book was published on the subject, and gradually the teaching of qualitative analysis assumed the shape and form with which we are all so well acquainted. But the present-day book on qualitative analysis differs widely from "Giessen Outlines" in this respect, that whereas in the latter the tables introduced are mere indications of the methods of separation to be employed, and are of such a nature that the student who did not think for himself must have been constantly in difficulties, in the book of the present day these tables have been worked out to the minutest detail. Every contingency is provided for; nothing is left to the originality of the student; and that which, no doubt, was once an excellent course has now become so hopelessly mechanical as to make it doubtful whether it retains anything of its former educational value.

The question which I now wish to consider more particularly is whether the system of training chemists which is at present adopted, with little variation, in our colleges and universities is a really satisfactory one, and whether it supplies the student with the kind of knowledge which will be of the most value to him in his future career.

Those who study chemistry may be roughly divided as to their future careers into two groups—those who become teachers and those who become technical chemists. Now, whether the student takes up either one or the other career, I think that it is clear that the objects to be aimed at in training him are to give him a sound knowledge of his subject, and especially to so arrange his studies as to bring out in every possible way his capacity for original thought.

A teacher who has no originality will hardly be successful, even though he may possess a very wide knowledge of what has already been done in the past. He will have little enthusiasm for his subject, and will continue to teach on the lines laid down by the text-books of the day, without himself materially improving the existing methods, and, above all, he will be unable, and will have no desire, to add to our store of knowledge by original investigation.

It is in the power of almost every teacher to do some research work, and it seems probable that the reason why more is not done by teachers is because the importance of research work was not sufficiently insisted on, and their original faculty was not sufficiently trained, at the schools and colleges where they received their education.

And these remarks apply with equal force to the student who subsequently becomes a technical chemist.

In the chemical works of to-day sound knowledge is essential, but originality is an even more important matter. A technical chemist without originality can scarcely rise to a responsible position in a large works; whereas a chemist who is capable of constantly improving the processes in operation, and of adding new methods to those in use, becomes so valuable that he can command his own terms.

Now, this being so, I think it is extraordinary that so many of the students who go through the prescribed course of training—say for the Bachelor of Science degree—not only show no originality themselves, but seem also to have no desire at the conclusion of their studies to engage in original investigation under the supervision of the teacher. That this is so is certainly my experience as a teacher examiner, and I feel sure that many other teachers will endorse this view of the case.

If we inquire into the reason for this deficiency in originality, we shall, I think, be forced to conclude that it is in a large measure due to the conditions of study and the nature of the courses through which the student is obliged to pass.

A well-devised system of quantitative analysis is undoubtedly valuable in teaching the student accurate manipulation, but it has always seemed to me that the long course of qualitative analysis which is usually considered necessary, and which generally precedes the quantitative work, is not the most satisfactory training for a student.

There can be no doubt that to many students qualitative analysis is little more than a mechanical exercise: the tables of separation are learnt by heart, and every substance is treated in precisely the same manner: such a course is surely not calculated to develop any original faculty which the student may possess. Then, again, when the student passes on to quantitative analysis, he receives elaborate instructions as to the little details he must observe in order to get an accurate result; and even after he has become familiar with the simpler determinations he rarely attempts, and indeed has no time to attempt, anything of the nature of an original investigation in qualitative or quantitative analysis. It indeed sometimes happens that a student at the end of his second year has never prepared a pure substance, and is often utterly ignorant of the methods employed in the separation of substances by crystallisation; he has never conducted a distillation, and has no idea how to investigate the nature and amounts of substances formed in chemical reactions; practically all his time has been taken up with analysis. That this is not the way to teach chemistry was certainly the opinion of Liebig, and in support of this I quote a paragraph bearing on the subject which occurs in a very interesting book on "Justus von Liebig: his Life and Work," written by W. A. Shenstone (pp. 175, 176).

"In his practical teaching Liebig laid great stress on the producing of chemical preparations; on the students preparing, that is to say, pure substances in good quantity from crude materials. The importance of this was, even in Liebig's time, often overlooked; and it was, he tells us, more common to find a man who could make a good analysis than to find one who could produce a pure preparation in the most judicious way."

"There is no better way of making one's self acquainted with the properties of a substance than by first producing it from the raw material, then converting it into its compounds, and so becoming acquainted with them. By the study of ordinary analysis one does not learn how to use the important methods of crystallisation, fractional distillation, nor acquire any considerable experience in the proper use of solvents. In short, one does not, as Liebig said, become a chemist."

One reason why the present system of training chemists has persisted so long is no doubt because it is a very convenient system: it is easily taught, does not require expensive apparatus, and, above all, it lends itself admirably for the purpose of competitive examination.

The system of examination which has been developed during the last twenty years has done much harm, and is a source of great difficulty to any conscientious teacher who is possessed of originality, and is desirous, particularly in special cases, of leaving the beaten track.

In our colleges and universities most of the students work for some definite examination—frequently for the Bachelor of Science degree—either at their own University or at the University of London.

For such degrees a perfectly definite course is prescribed and must be followed, because the questions which the candidate will have to answer at his examination are based on a syllabus which is either published or is known by precedent to be required. The course which the teacher is obliged to teach is thus placed beyond his individual power of alteration, except in minor details, and originality in the teacher is thereby discouraged: he knows that all students must face the same examination, and he must urge the backward man through exactly the same course as his more talented neighbour.

In almost all examinations salts or mixtures of salts are given for qualitative analysis. "Determine the constituents of the simple salt A and of the mixture B" is a favourite examination formula; and as some practical work of this sort is sure to be set, the teacher knows that he must contrive to get one and all of his students into a condition to enable them to answer such questions.

If, then, one considers the great amount of work which is required from the present-day student, it is not surprising that every aid to rapid preparation for examination should be accepted with delight by the teacher; and thus it comes about that tables are elaborated in every detail, not only for qualitative analysis in inorganic chemistry, but, what is far worse, for the detection of some arbitrary selection of organic substances which may be set in the syllabus for the examination. I question whether any really competent teacher will be found to recommend this system as one of educational value or calculated to bring out and train the faculty of original thought in students.

If, then, the present system is so unsatisfactory, it will naturally be asked, How are students to be trained, and how are they to be examined so as to find out the extent of the knowledge of their subject which they have acquired?

In dealing with the first part of the question—that is, the training best suited to chemists—I can, of course, only give my own views on the subject—views which, no doubt, may differ much from those of many of the teachers present at this meeting. The objects to be attained are, in my opinion, to give the student a sufficient knowledge of the broad facts of chemistry, and at the same time so to arrange his practical work in particular as to always have in view the training of his faculty of original thought.

I think it will be conceded that any student, if he is to make his mark in chemistry by original work, must ultimately specialise in some branch of the subject. It may be possible for some great minds to do valuable original work in more than one branch of chemistry, but these are the exceptions; and as time goes on, and the mass of facts accumulates, this will become more and more impossible. Now a student at the commencement of his career rarely knows which branch of the subject will fascinate him most, and I think, therefore, that it is necessary, in the first place, to do all that is possible to give him a thorough grounding in all branches of the subject. In my opinion the student is taken over too much ground in the lecture courses of the present day: in inorganic chemistry, for example, the study of the rare metals and their reactions might be dispensed with, as well as many of the more difficult chapters of physical chemistry, and in organic chemistry such complicated problems as the constitutions of uric acid and the members of the camphor and terpene series, &c., might well be left out. As matters stand now, instruction must be given on these subjects simply because questions bearing on them will probably be asked at the examination.

And here, perhaps, I might make a confession, in which I do not ask my fellow-teachers to join me. My name is often attached to chemistry papers which I should be sorry to have to answer; and it seems to me the standard of examination papers, and especially of Honours examination papers, is far too high. Should we demand a pitch of knowledge which our own experience tells us cannot be maintained for long?

In dealing with the question of teaching practical chemistry, it may be hoped, in the first place, that in the near future a sound training will be given in elementary science in most schools, very much on the lines which I mentioned in the first part of this address. The student will then be in a fit state to undergo a thoroughly satisfactory course of training in inorganic chemistry during his first two years at college. Without wishing in any way to map out a definite course, I may be allowed to suggest that instead of much of the usual qualitative and quantitative analysis, practical exercises similar to the following will be found to be of much greater educational value.

(1) The careful experimental demonstration of the fundamental laws of chemistry and physical chemistry.

(2) The preparation of a series of compounds of the more important metals, either from their more common ores or from the metals themselves. With the aid of the compounds thus prepared the reactions of the metals might be studied and the similarities and differences between the different metals then carefully noted.

(3) A course in which the student should investigate in certain selected cases: (*a*) the conditions under which action takes place; (*b*) the nature of the products formed; (*c*) the yield obtained. If he were then to proceed to prepare each product in a state of purity, he would be doing a series of exercises of the highest educational value.

(4) The determination of the combining weights of some of the more important metals. This is in most cases comparatively simple, as the determination of the combining weights of selected metals can be very accurately carried out by measuring the hydrogen evolved when an acid acts upon them.

Many other exercises of a similar nature will readily suggest themselves, and in arranging the course every effort should be made to induce the student to consult original papers, and to avoid as far as possible any tendency to mere mechanical work.

The exact nature of such a course must, however, necessarily be left very much in the hands of the teacher, and the details will no doubt require much consideration; but I feel sure that a course of practical inorganic chemistry could be constructed which, while teaching all the important facts which it is necessary for the student to know, will, at the same time, constantly tend to develop his faculty of original thought.

Supposing such a course were adopted (and the experiment is well worth trying), there still remains the problem of how the student who has had this kind of training is to be examined.

With regard to his theoretical work there would be no difficulty, as the examination could be conducted on much the same lines as at the present time. In the case of the practical examination I have long felt that the only satisfactory method of arriving at the value of a student's practical knowledge is by the inspection of the work which he has done during the whole of his course of study, and not by depending on the results of one or two days' set examination. I think that most examiners will agree with me that the present system of examination in practical chemistry is highly unsatisfactory. This is perhaps not so apparent in the case of the qualitative analysis of the usual simple salt or mixture; but when the student has to do a quantitative exercise, or when a problem is set, the results sent in are frequently no indication of the value of the student's practical work. Leaving out of the question the possibility of the student being in indifferent health during the short period of the practical examination, it not infrequently happens that he, in his excitement, has the misfortune to upset a beaker when his quantitative determination is nearly finished, and as a result he loses far more marks than he should do for so simple an accident.

Again, in attacking a problem he has usually only time to try one method of solution, and if this does not yield satisfactory results he again loses marks; whereas in the ordinary course of his practical work, if he were to find that the first method was faulty, he would try other methods until he ultimately arrived at the desired result.

It is difficult to see why such an unsatisfactory system as this might not be replaced by one of inspection which I think could easily be so arranged as to work well.

A student taking, say, a three years' course for the degree of Bachelor of Science might be required to keep very careful notes of all the practical work which he does during this course, and in order to avoid fraud his notebook could from time to time be initialled by the professor or demonstrator in charge of the laboratory. An inspection of these notebooks could then be made at suitable times by the examiners for the degree, by which means a very good idea would be obtained of the scope of the work which the student had been engaged in, and if thought necessary a few questions could easily be asked in regard to the work so presented. Should the examiners wish to further test the candidate by giving him an examination, I submit that it would be much better to set him some exercise of the nature of a simple original investigation, and to allow him two or three weeks to carry this out, than to depend on the hurried work of two or three days.

The object which I had in view in writing this Address was to call attention to the fact that our present system of training in chemistry does not appear to develop in the student the power of conducting original research, and at the same time to endeavour to suggest some means by which a more satisfactory state of things might be brought about. I have not been able, within the limits of this Address, to consider the conditions of study during the third year of the student's career at college, or to discuss the increasing necessity for extending that course and insisting on the student carrying out an adequate original investigation before granting him a degree, but I hope on some future occasion to have the opportunity of returning to this very important part of the subject. If any of the suggestions I have made should prove to be of practical value, and should lead to the production of more original research by our students, I shall feel that a useful purpose has been served by bringing this matter before this Section. In concluding I wish to thank Prof. H. B. Dixon, Prof. F. S. Kipping and others, for many valuable suggestions, and my thanks are especially due to Dr. Bevan Lean for much information which he gave me in connection with that part of this Address which deals with the teaching of chemistry in schools.

## SECTION C.

### GEOLOGY.

### OPENING ADDRESS BY PROF. W. J. SOLLAS, D.SC., LL.D., F.R.S., PRESIDENT OF THE SECTION.

### *Evolutional Geology.*

THE close of one century, the dawn of another, may naturally suggest some brief retrospective glance over the path along which our science has advanced, and some general survey of its present position from which we may gather hope of its future progress; but other connection with geology the beginnings and endings of centuries have none. The great periods of movement have hitherto begun, as it were, in the early twilight hours, long before the dawn. Thus the first step forward, since which there has been no retreat, was taken by Steno in the year 1669; more than a century elapsed before James Hutton (1785) gave fresh energy and better direction to the faltering steps of the young science; while it was less than a century later (1863) when Lord Kelvin brought to its aid the powers of the higher mathematics and instructed it in the teachings of modern physics. From Steno onward the spirit of geology was catastrophic; from Hutton onward it grew increasingly uniformitarian; from the time of Darwin and Kelvin it has become evolutional. The ambiguity of the word "uniformitarian" has led to a good deal of fruitless logomachy, against which it may be as well at once to guard by indicating the sense in which it is used here. In one way we are all uniformitarians, *i.e.* we accept the doctrine of the "uniform action of natural causes," but, as applied to geology, uniformity means more than this. Defined in the briefest fashion it is the geology of Lyell. Hutton had given us a "Theory of the Earth," in its main outlines still faithful and true; and this Lyell spent his life in illustrating and advocating; but as so commonly happens the zeal of the disciple outran the wisdom of the master, and mere opinions were insisted on as necessary dogma. What did it matter if Hutton as a result of his inquiries into terrestrial history had declared that he found no vestige of a beginning, no prospect of an end? It would have been marvellous if he had! Consider that when Hutton's "Theory" was published William Smith's famous discovery had not been made, and that nothing was then known of the orderly succession of forms of life, which it is one of the triumphs of geology to have revealed; consider, too, the existing state of physics at the time, and that the modern theories of energy had still to be formulated; consider also that spectroscopy had not yet lent its aid to astronomy and the consequent ignorance of the nature of nebulæ; and then, if you will, cast a stone at Hutton. With Lyell, however, the case was different: in pressing his uniformitarian creed upon geology he omitted to take into account the great advances made by its sister sciences, although he had knowledge of them, and thus sinned against the light. In the last edition of the famous "Principles" we read: "It is a favourite dogma of some physicists that not only the earth, but the sun itself, is continually losing a portion of its heat, and that as there is no known source by which it can be restored we can foresee the time when all life will cease to exist on this planet, and on the other hand we can look back to a period when the heat was so intense as to be incompatible with the existence of any organic beings such as are known to us in the living or fossil world. . . . A geologist in search of some renovating power by which the amount of heat may be made to continue unimpaired for millions of years, past and future, in the solid parts of the earth . . . has been compared by an eminent physicist to one who dreams he can discover a source of perpetual motion and invent a clock with a self-winding apparatus. *But why should we despair of detecting proofs of such regenerating and self-sustaining power in the works of a Divine Artificer?*" Here we catch the true spirit of uniformity; it admittedly regards the universe as a self-winding clock, and barely conceals a conviction that the clock was warranted to keep true Greenwich time. The law of the dissipation of energy is not a dogma, but a doctrine drawn from observation, while the uniformity of Lyell is in no sense an induction: it is a dogma in the narrowest sense of the word, unproved, incapable of proof; hence perhaps its power upon the human mind; hence also the transitoriness of that power. Again, it is only by restricting its inquiries to the stratified rocks of our planet that the dogma of uniformity can be maintained with any pretence of argument. Directly we begin to search the heavens the possibility, nay even the likelihood, of the nebular origin of our system, with all that it involves, is borne in upon us. Lyell therefore consistently refused to extend his gaze beyond the rocks beneath his feet, and was thus led to do a serious injury to our science: he severed it from cosmogony, for which he entertained and expressed the most profound contempt, and from the mutilation thus inflicted geology is only at length making a slow and painful recovery. Why do I dwell on these facts? To depreciate Lyell? By no means. No one is more conscious than I of the noble service which Lyell rendered to our cause: his reputation is of too robust a kind to suffer from my unskilful handling, and the fame of his solid contributions to science will endure long after these controversies are forgotten. The echoes of the combat are already dying away, and uniformitarians, in the sense already defined, are now no more; indeed, were I to attempt to exhibit any distinguished living geologist as a still surviving supporter of the narrow Lyellian creed, he would probably feel, if such a one there be, that I was unfairly singling him out for unmerited obloquy.

Our science has become evolutional, and in the transformation has grown more comprehensive: her petty parochial days are done, she is drawing her provinces closer around her, and is fusing them together into a united and single commonwealth—the science of the earth.

Not merely the earth's crust, but the whole of earth-knowledge is the subject of our research. To know all that can be known about our planet, this, and nothing less than this, is its aim and scope. From the morphological side geology inquires, not only into the existing form and structure of the earth, but also into the series of successive morphological states through which it has passed in a long and changeful development. Our science inquires also into the distribution of the earth in time and space; on the physiological side it studies the movements and activities of our planet; and not content with all this it extends its researches into ætiology and endeavours to arrive at a science of causation. In these pursuits geology calls all the other sciences to her aid. In our commonwealth there are no outlanders; if an eminent physicist enter our territory we do not begin at once to prepare for war, because the very fact of his undertaking a geological inquiry of itself confers upon him all the duties and privileges of citizenship. A physicist studying geology is by definition a geologist. Our only regret is, not that physicists occasionally invade our borders, but that they do not visit us oftener and make closer acquaintance with us.

### *Early History of the Earth: First Critical Period.*

If I am bold enough to assert that cosmogony is no longer alien to geology, I may proceed further, and taking advantage of my temerity pass on to speak of things once not permitted to us. I propose, therefore, to offer some short account of the early stages in the history of the earth. Into its nebular origin we need not inquire—that is a subject for astronomers. We are content to accept the infant earth from their hands as a molten globe ready made, its birth from a gaseous nebula duly certified. If we ask, as a matter of curiosity, what was the origin of the nebula, I fear even astronomers cannot tell us. There is an hypothesis which refers it to the clashing of meteorites, but in the form in which this is usually presented it does not help us much. Such meteorites as have been observed to penetrate our atmosphere and to fall on to the surface of tha earth prove on examination to have had an eventful history of their own of which not the least important chapter was a passage through a molten state; they would thus appear to be the products rather than the progenitors of a nebula.

We commence our history, then, with a rapidly-rotating molten planet, not impossibly already solidified about the centre and surrounded by an atmosphere of great depth, the larger part of which was contributed by the water of our present oceans, then existing in a state of gas. This atmosphere, which exerted a pressure of something like 5000 lb. to the square inch, must have played a very important part in the evolution of our planet. The molten exterior absorbed it to an extent which depended on the pressure, and which may some day be learnt from experiment. Under the influence of the rapid rotation of the earth the atmosphere would be much deeper in equatorial than polar regions, so that in the latter the loss of heat by radiation would be in excess. This might of itself lead to convectional currents in the molten ocean. The effect on the atmosphere is very difficult to trace, but it is obvious that if a high-pressure area originated over some cooler region of the ocean, the winds blowing out of it would drive before them the cooler superficial layers of molten material, and as these were replaced by hotter lava streaming from below, the tendency would be to convert the high into a low-pressure area, and to reverse the direction of the winds. Conversely under a low-pressure area the in-blowing winds would drive in the cooler superficial layers of molten matter that had been swept away from the anticyclones. If the difference in pressure under the cyclonic and anticyclonic areas were considerable, some of the gas absorbed under the anticyclones might escape beneath the cyclones, and in a later stage of cooling might give rise to vast floating islands of scoria. Such islands might be the first foreshadowings of the future continents. Whatever the ultimate effect of the reaction of the winds on the currents of the molten ocean, it is probable that some kind of circulation was set up in the latter. The universal molten ocean was by no means homogeneous: it was constantly undergoing changes in composition as it reacted chemically with the internal metallic nucleus; its currents would streak the different portions out in directions which in the northern hemisphere would run from north-east to south-west, and thus the differences which distinguish particular petrological regions of our planet may have commenced their existence at a very early stage. Is it possible that as our knowledge extends we shall be able by a study of the distribution of igneous rocks and minerals to draw some conclusions as to the direction of these hypothetical lava currents? Our planet was profoundly disturbed by tides, produced by the sun; for as yet there was no moon; and it has been suggested that one of its tidal waves rose to a height so great as to sever its connection with the earth and to fly off as the infant moon. This event may be regarded as marking the first critical period, or catastrophe if we please, in the history of our planet. The career of our satellite, after its escape from the earth, is not known till it attained a distance of nine terrestrial radii; after this its progress can be clearly followed. At the eventful time of parturition the earth was rotating, with a period of from two to four hours, about an axis inclined at some 11° or 12° to the ecliptic. The time which has elapsed since the moon occupied a position nine terrestrial radii distant from the earth is at least fifty-six to fifty-seven millions of years, but may have been much more. Prof. Darwin's story of the moon is certainly one of the most beautiful contributions ever made by astronomy to geology, and we shall all concur with him when he says, "A theory reposing on *veræ causæ*, which brings into quantitative correlation the length of the present day and month, the obliquity of the ecliptic, and the inclination and eccentricity of the lunar orbit, must, I think, have strong claims to acceptance."

The majority of geologists have long hankered after a metallic nucleus for the earth, composed chiefly, by analogy with meteorites, of iron. Lord Kelvin has admitted the probable existence of some such nucleus, and lately Prof. Wiechert has furnished us with arguments—"powerful" arguments Prof. Darwin terms them—in support of its existence. The interior of the earth for four-fifths of the radius is composed, according to Prof. Wiechert, chiefly of metallic iron, with a density of 8·2; the outer envelope, one fifth of the radius, or about 400 miles in thickness, consists of silicates, such as we are familiar with in igneous rocks and meteorites, and possesses a density of 3·2. It was from this outer envelope when molten that the moon was trundled off, twenty-seven miles in depth going to its formation. The density of this material, as we have just seen, is supposed to be 3·2; the density of the moon is 3·39, a close approximation, such difference as exists being completely explicable by the comparatively low temperature of the moon.

The outer envelope of the earth which was drawn off to form the moon was, as we have seen, charged with steam and other gases under a pressure of 5000 lb. to the square inch; but as the satellite wandered away from the parent planet this pressure continuously diminished. Under these circumstances the moon would become as explosive as a charged bomb, steam would burst forth from numberless volcanoes, and while the face of the moon might thus have acquired its existing features, the ejected material might possibly have been shot so far away from its origin as to have acquired an independent orbit. If so we may ask whether it may not be possible that the meteorites, which sometimes descend upon our planet, are but portions of its own envelope returning to it. The facts that the average specific gravity of those meteorites which have been seen to fall is not much above 3·2, and that they have passed through a stage of fusion, are consistent with this suggestion.

### *Second Critical Period. "Consistentior Status."*

The solidification of the earth probably became completed soon after the birth of the moon. The temperature of its surface at the time of consolidation was about 1170° C., and it was therefore still surrounded by its primitive deep atmosphere of steam and other gases. This was the second critical period in the history of the earth, the stage of the "consistentior status," the date of which Lord Kelvin would rather know than that of the Norman Conquest, though he thinks it lies between twenty and forty millions of years ago, probably nearer twenty than forty.

Now that the crust was solid there was less reason why movements of the atmosphere should be unsteady, and definite regions of high and low pressure might have been established. Under the high-pressure areas the surface of the crust would be depressed; correspondingly under the low-pressure areas it would be raised; and thus from the first the surface of the solid earth might be dimpled and embossed."[1]

### *Third Critical Period. Origin of the Oceans.*

The cooling of the earth would continuously progress, till the temperature of the surface fell to 370° C., when that part of the atmosphere which consisted of steam would begin to liquefy; then the dimples on the surface would soon become filled with superheated water, and the pools so formed would expand and deepen, till they formed the oceans. This is the third critical stage in the history of the earth, dating, according to Prof. Joly, from between eighty and ninety millions of years ago. With the growth of the oceans the distinction between land and sea arose—in what precise manner we may proceed to inquire. If we revert to the period of the "consistentior status," when the earth had just solidified, we shall find, according to Lord Kelvin, that the temperature continuously increased from the surface, where it was 1170° C., down to a depth of twenty-five miles, where it was about 1430° C., or 260° C. above the fusion point of the matter, forming the crust.

---

[1] It would be difficult to discuss with sufficient brevity the probable distribution of these inequalities, but it may be pointed out that the moon is possibly responsible, and that in more ways than one, for much of the existing geographical asymmetry.

That the crust at this depth was not molten but solid is to be explained by the very great pressure to which it was subjected—just so much pressure, indeed, as was required to counteract the influence of the additional 260° C. Thus if we could have reduced the pressure on the crust we should have caused it to liquefy; by restoring the pressure it would resolidify. By the time the earth's surface had cooled down to 370° C. the depth beneath the surface at which the pressure just kept the crust solid would have sunk some slight distance inwards, but not sufficiently to affect our argument.

The average pressure of the primitive atmosphere upon the crust can readily be calculated by supposing the water of the existing oceans to be uniformly distributed over the earth's surface, and then by a simple piece of arithmetic determining its depth; this is found to be 1·718 miles, the average depth of the oceans being taken at 2·393 miles. Thus the average pressure over the earth's surface, immediately before the formation of the oceans, was equivalent to that of a column of water 1·718 miles high on each square inch. Supposing that at its origin the ocean were all "gathered together into one place," and "the dry land appeared," then the pressure over the ocean floor would be increased from 1·718 miles to 2·393 miles, while that over those portions of the crust that now formed the land would be diminished by 1·718 miles. This difference in pressure would tend to exaggerate those faint depressions which had arisen under the primitive anti-cyclonic areas, and if the just solidified material of the earth's crust were set into a state of flow, it might move from under the ocean into the bulgings which were rising to form the land, until static equilibrium were established. Under these circumstances the pressure of the ocean would be just able to maintain a column of rock 0·886 miles in height, or ten twenty-sevenths of its own depth. It could do no more; but in order that the dry land may appear some cause must be found competent either to lower the ocean bed the remaining seventeen twenty-sevenths of its full depth, or to raise the continental bulgings to the same extent. Such a cause may, I think, be discovered in a further effect of the reduction in pressure over the continental areas. Previous to the condensation of the ocean, these, as we have seen, were subjected to an atmospheric pressure equal to that of a column of water 1·718 miles in height. This pressure was contributory to that which caused the outer twenty-five miles of the earth's crust to become solid; it furnished, indeed, just about one fortieth of that pressure, or enough to raise the fusion point 6° C. What, then, might be expected to happen when the continental area was relieved of this load? Plainly a liquefaction and corresponding expansion of the underlying rock.

But we will not go so far as to assert that actual liquefaction would result; all we require for our explanation is a great expansion; and this would probably follow whether the crust were liquefied or not. For there is good reason to suppose that when matter at a temperature above its ordinary fusion point is compelled into the solid state by pressure, its volume is very responsive to changes either of pressure or temperature. The remarkable expansion of liquid carbon dioxide is a case in point: 120 volumes of this fluid at —20° C. become 150 volumes at 33° C.; a temperature just below the critical point. A great change of volume also occurs when the material of igneous rocks passes from the crystalline state to that of glass; in the case of diabase[1] the difference in volume of the rock in the two states at ordinary temperatures is 13 per cent. If the relief of pressure over the site of continents were accompanied by volume changes at all approaching this, the additional elevation of seventeen twenty-sevenths required to raise the land to the sea-level would be accounted for.[2] How far down beneath the surface the unloading of the continents would be felt it is difficult to say, though the problem is probably not beyond the reach of mathematical analysis; if it affected an outer envelope twenty-five miles in thickness, a linear expansion of 4 per cent. would suffice to explain the origin of ocean basins. If now we refer to the dilatation determined by Carl Barus for rise in temperature in the case of diabase, we find that between 1093° and 1112° C. the increase in volume is 3·3 per cent. As a further factor in deepening the ocean basins may be included the compressive effect of the increase in load over the ocean floor: this increase is equal to the pressure of a column of water 0·675 mile in height, and its effect in raising the fusion point would be 2° C., from which we may gain some kind of idea of the amount of compression it might produce on the yielding interior of the crust. To admit that these views are speculative will be to confess nothing; but they certainly account for a good deal. They not only give us ocean basins, but basins of the kind we want, that is, to use a crude comparison once made by the late Dr. Carpenter, basins of a tea-tray form, having a somewhat flat floor and steeply sloping sides; they also help to explain how it is that the value of gravity is greater over the ocean than over the land.

The ocean when first formed would consist of highly heated water, and this, as is well known, is an energetic chemical reagent when brought into contact with silicates like those which formed the primitive crust. As a result of its action saline solutions and chemical deposits would be formed; the latter, however, would probably be of no great thickness, for the time occupied by the ocean in cooling to a temperature not far removed from the present would probably be included within a few hundreds of years.

### *The Stratified Series.*

The course of events now becomes somewhat obscure, but sooner or later the familiar processes of denudation and the deposition started into activity, and have continued acting uninterruptedly ever since. The total maximum thickness of the sedimentary deposits, so far as I can discover, appears to amount to no less than 50 miles, made up as follows:—

| | Feet | |
|---|---|---|
| Recent and Pleistocene ... | 4,000 ... | Man. |
| Pliocene ... ... ... ... | 5,000 ... | Pithecanthropus. |
| Miocene ... ... ... ... | 9,000 ... | |
| Oligocene ... ... ... ... | 12,000 ... | |
| Eocene ... ... ... ... | 12,000 | Eutheria. |
| Cretaceous .. ... ... ... | 14,000 ... | |
| Jurassic ... ... ... ... | 8,000 ... | |
| Trias ... ... ... ... ... | 13,000 ... | Mammals. |
| Permian ... ... ... ... | 12,000 ... | Reptiles. |
| Carboniferous ... ... ... | 24,000 ... | Amphibia. |
| Devonian ... ... ... ... | 22,000 ... | Fish. |
| Silurian ... ... ... ... | 15,000 ... | |
| Ordovician ... ... ... ... | 17,000 ... | |
| Cambrian ... ... ... ... | 16,000 ... | Invertebrata. |
| Keeweenawan ... ... ... | 50,000 ... | |
| Penokee ... ... ... ... | 14,000 ... | |
| Huronian ... ... ... ... | 18,000 ... | |

Geologists, impressed with the tardy pace at which sediments appear to be accumulating at the present day, could not contemplate this colossal pile of strata without feeling that it spoke of an almost inconceivably long lapse of time. They were led to compare its duration with the distances which intervene between the heavenly bodies; but while some chose the distance of the nearest fixed star as their unit, others were content to measure the years in terms of miles from the sun.

### *Evolution of Organisms.*

The stratified rocks were eloquent of time, and not to the geologist alone; they appealed with equal force to the biologist. Accepting Darwin's explanation of the origin of species, the present rate at which form flows to form seemed so slow as almost to amount to immutability. How vast then must have been the period during which by slow degrees and innumerable stages the protozoon was transformed into the man! And if we turn to the stratified column, what do we find? Man, it is true, at the summit, the oldest fossiliferous rocks 34 miles lower down, and the fossils they contain already representing most of the great classes of the Invertebrata, including Crustacea and Worms. Thus the evolution of the Vertebrata alone is known to have occupied a period represented by a thickness of 34 miles of sediment. How much greater, then, must have been the interval required for the elaboration of the whole organic world! The human mind, dwelling on such considerations as these, seems at times to have been affected by a sur-excitation of the imagination, and a consequent paralysis of the understanding, which led to a refusal to measure geological time by years at all, or to reckon by anything less than "eternities."

---

[1] C. Barus so names the material on which he experimented; apparently the rock is a fresh dolerite without olivine.

[2] Prof. Fitzgerald has been kind enough to express part of the preceding explanation in a more precise manner for me. He writes: "It would require a very nice adjustment of temperatures and pressures to work out in the simple way you state it; but what is really involved is that in a certain state diabase (and everything that changes state with a considerable change of volume) has an enormous isothermal compressibility. Although this is very enormous in the case of bodies which melt suddenly, like ice, it would also involve very great compressibilities in the case of bodies even which melted gradually, if they did so at all quickly, *i.e.* within a small range of temperature. What you postulate, then, is that at a certain depth diabase is soft enough to be squeezed from under the oceans, and that, being near its melting point, the small relief of pressure is accompanied by an enormous increase in volume which helped to raise the continents. Now that I have written the thing out in my own way it seems very likely. It is, anyway, a suggestion quite worthy of serious consideration, and a process that in some places must almost certainly have been in operation, and maybe is still operative. Looking at it again, I hardly think it is quite likely that there is or could be much squeezing sideways of liquid or other viscous material from under one place to another, because the elastic yielding of the inside of the earth would be much quicker than any flow of this kind. This would only modify your theory, because the diabase that expands so much on the relief of pressure might be that already under the land, and raising up this latter, partly by being pushed up itself by the elastic relief of the inside of the earth and partly by its own enormous expansibility near its melting point. The action would be quite slow, because it would cool itself so much by its expansion that it would have to be warmed up from below, or by tidal earth-squeezing, or by chemical action, before it could expand isothermally."

### *Geologic Periods of Time.*

After the admirable Address of your President last year it might be thought needless for me to again enter into a consideration of this subject; it has been said, however, that the question of geological time is like the Djin in Arabian tales, and will irrepressibly come up again for discussion, however often it is disposed of. For my part I do not regard the question so despondingly, but rather hope that by persevering effort we may succeed in discovering the talisman by which we may compel the unwilling Djin into our service. How immeasurable would be the advance of our science could we but bring the chief events which it records into some relation with a standard of time!

Before proceeding to the discussion of estimates of time drawn from a study of stratified rocks let us first consider those which have been already suggested by other data. These are as follows:—(1) Time which has elapsed since the separation of the earth and moon, fifty-six millions of years, minimum estimate by Prof. G. H. Darwin. (2) Since the "consistentior status," twenty to forty millions (Lord Kelvin). (3) Since the condensation of the oceans, eighty to ninety millions, maximum estimate by Prof. J. Joly.

It may be at once observed that these estimates, although independent, are all of the same order of magnitude, and so far confirmatory of each other. Nor are they opposed to conclusions drawn from a study of stratified rocks; thus Sir Archibald Geikie, in his Address to this Section last year, affirmed that, so far as these were concerned, one hundred millions of years might suffice for their formation. There is then very little to quarrel about, and our task is reduced to an attempt, by a little stretching and a little paring, to bring these various estimates into closer harmony.

Prof. Darwin's estimate is admittedly a minimum; the actual time, as he himself expressly states, "may have been much longer." Lord Kelvin's estimate, which he would make nearer twenty than forty millions, is founded on the assumption that since the period of the "consistentior status" the earth has cooled simply as a solid body, the transference of heat from within outwards having been accomplished solely by conduction.[1]

It may be at once admitted that there is a large amount of truth in this assumption; there can be no possible doubt that the earth reacts towards forces applied for a short time as a solid body. Under the influence of the tides it behaves as though it possessed a rigidity approaching that of steel, and under sudden blows, such as those which give rise to earthquakes, with twice this rigidity, as Prof. Milne informs me. Astronomical considerations lead to the conclusion that its effective rigidity has not varied greatly for a long period of past time.

Still, while fully recognising these facts, the geologist knows —we all know—that the crust of the earth is not altogether solid. The existence of volcanoes by itself suggests the contrary, and although the total amount of fluid material which is brought from the interior to the exterior of the earth by volcanic action may be, and certainly is, small—from data given by Prof. Penck, I estimate it as equivalent to a layer of rock uniformly distributed 2 mm. thick per century; yet we have every reason to believe that volcanoes are but the superficial manifestation of far greater bodies of molten material which lie concealed beneath the ground. Even the wide areas of plutonic rock, which are sometimes exposed to view over a country that has suffered long-continued denudation, are merely the upper portion of more extensive masses which lie remote from view. The existence of molten material within the earth's crust naturally awakens a suspicion that the process of cooling has not been wholly by conduction, but also to some slight extent by convection, and to a still greater extent by the bodily migration of liquid lava from the deeper layers of the crust towards the surface.

The existence of local reservoirs of molten rock within the crust is even still more important in another connection, that is, in relation with the supposed "average rate of increase of temperature with descent below the ground." It is doubtful whether we have yet discovered a rate that in any useful sense can be spoken of as "average." The widely divergent views of different authorities as to the presumed value of this rate may well lead to reflection. The late Prof. Prestwich thought a rise of 1° F. for every 45 feet of descent below the zone of constant temperature best represented the average; Lord Kelvin in his earlier estimates has adopted a value of 1° F. for every 51 feet; the Committee of this Association appointed to investigate this question arrived at a rate of 1° F. for every 60 feet of descent; Mr. Clarence King has made calculations in which a rate of 1° F. for 72 feet is adopted; a re-investigation of recorded measurements would, I believe, lead to a rate of 1° F. in 80 or 90 feet as more closely approaching the mean. This would raise Lord Kelvin's estimate to nearly fifty millions of years.

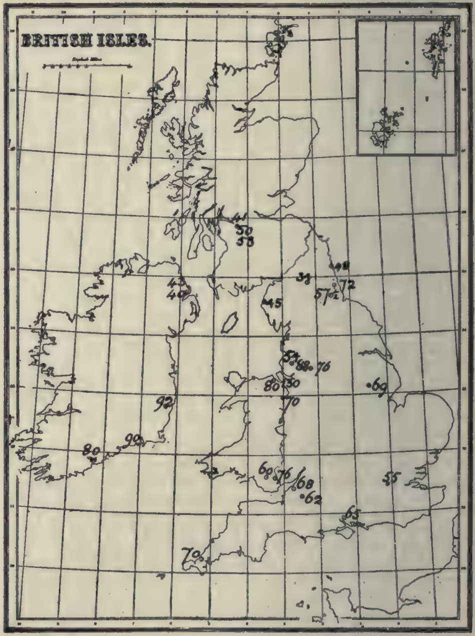

FIG. 1.—Map of the British Isles, showing the distribution of rates of increase of temperature with descent. The rates are taken from the "British Association Report," except in the case of those in the south of Ireland.

When from these various averages we turn to the observations on which they are based, we encounter a surprising divergence of extremes from the mean; thus in the British Isles alone the rate varies from 1° F. in 34 feet to 1° F. in 92 feet, or in one case to 1° F. in 130 feet. It has been suggested, and to some extent shown, that these irregularities may be connected with differences in conductivity of the rocks in which the observations were made, or to the circulation of underground water; but many cases exist which cannot be explained away in such a manner, but are suggestive of some deep-seated cause, such as the distribution of molten matter below the ground. Inspection of the accompanying map of the British Isles, on which the rates of increase in different localities have been plotted, will afford some evidence of the truth of this view. Comparatively low rates of increase are found over Wales and in the province of Leinster, districts of relatively great stability, the remnants of an island that have in all probability stood above the sea ever since the close of the Silurian period. To the north of this, as we enter a region which was subject to volcanic disturbances during the Tertiary period, the rate increases.

---

[1] The heat thus brought to the surface would amount to one-seventeenth of that conveyed by conduction.

It is obvious that in any attempt to estimate the rate at which the earth is cooling as a solid body the disturbing influence of subterranean lakes of molten rock must as far as possible be eliminated; but this will not be effected by taking the accepted mean of observed rates of increase of temperature: such an average is merely a compromise, and a nearer approach to a correct result will possibly be attained by selecting some low rate of increase, provided it be based on accurate observations.

It is extremely doubtful whether an area such as the British Isles, which has so frequently been the theatre of volcanic activity and other subterranean disturbance, is the best fitted to afford trustworthy results; the Archæan nucleus of a continent might be expected to afford surer indications. Unfortunately the hidden treasures of the earth are seldom buried in these regions, and bore-holes in consequence have rarely been made in them. One exception is afforded by the copper-bearing district of Lake Superior, and in one case, that of the Calumet and Hecla mine, which is 4580 feet in depth, the rate of increase, as determined by Prof. A. Agassiz, was 1° F. for every 223·7 feet. The Bohemian "horst" is a somewhat ancient part of Europe, and in the Przibram mines, which are sunk in it, the rate was 1° F. for every 126 feet of descent. In the light of these facts it would seem that geologists are by no means compelled to accept the supposed mean rate of increase of temperature with descent into the crust as affording a safe guide to the rate of cooling of a solid globe; and if the much slower rate of increase observed in the more ancient and more stable regions of the earth has the importance which is suggested for it, then Lord Kelvin's estimate of the date of the "consistentior status" may be pushed backwards into a remoter past.

If, as we have reason to hope, Lord Kelvin's somewhat contracted period will yield to a little stretching, Prof. Joly's, on the other hand, may take some paring. His argument, broadly stated, is as follows. The ocean consisted at first of fresh water; it is now salt, and its saltness is due to the dissolved matter that is constantly being carried into it by rivers. If, then, we know the quantity of salt which the rivers bring down each year into the sea, it is easy to calculate how many years they have taken to supply the sea with all the salt it at present contains. For several reasons it is found necessary to restrict attention to one only of the elements contained in sea salt: this is sodium. The quantity of sodium delivered to the sea every year by rivers is about 160,000,000 tons; but the quantity of sodium which the sea contains is at least ninety millions of times greater than this. The period during which rivers have been carrying sodium into the sea must therefore be about ninety millions of years. Nothing could be simpler; there is no serious flaw in the method, and Prof. Joly's treatment of the subject is admirable in every way; but of course in calculations such as this everything depends on the accuracy of the data, which we may therefore proceed to discuss. Prof. Joly's estimate of the amount of sodium in the ocean may be accepted as sufficiently near the truth for all practical purposes. We may therefore pass on to the other factor, the annual contribution of sodium by river water. Here there is more room for error. Two quantities must be ascertained: one the quantity of water which the rivers of the world carry into the sea, the other the quantity or proportion of sodium present in this water. The total volume of water discharged by rivers into the ocean is estimated by Sir John Murray as 6524 cubic miles. The estimate being based on observations of thirty-three great rivers, although only approximate, it is no doubt sufficiently exact; at all events such alterations as it is likely to undergo will not greatly affect the final result. When, however, we pass to the last quantity to be determined, the chemical composition of average river water, we find that only a very rough estimate is possible, and this is the more unfortunate because changes in this may very materially affect our conclusions. The total quantity of river water discharged into the sea is, as we have stated, 6524 cubic miles. The average composition of this water is deduced from analyses of nineteen great rivers, which altogether discharge only 488 cubic miles, or 7·25 per cent. of the whole. The danger in using this estimate is twofold: in the first place 7·25 is too small a fraction from which to argue to the remaining 92·75 per cent., and, next, the rivers which furnish it are selected rivers, *i.e.*, they are all of large size. The effect of this is that the drainage of the volcanic regions of the earth is not sufficiently represented, and it is precisely this drainage which is richest in sodium salts. The lavas and ashes of active volcanoes rapidly disintegrate under the energetic action of various acid gases, and among volcanic exhalations sodium chloride has been especially noticed as abundant. Consequently we find that while the proportion of sodium in Prof. Joly's average river water is only 5·73 per million, in the rivers of the volcanic island of Hawaii it rises to 24·5 per million (Walter Maxwell, "Lavas and Soils of the Hawaiian Islands," p. 170). No doubt the area occupied by volcanoes is trifling compared with the remaining land surface. On the other hand the majority of volcanoes are situated in regions of copious rainfall, of which they receive a full share owing to their mountainous form. Much of the fallen rain percolates through the porous material of the cone, and, richly charged with alkalies, finds its way by underground passages towards the sea, into which it sometimes discharges by submarine springs.

Again, several considerations lead to the belief that the supply of sodium to the ocean has proceeded, not at a uniform, but at a gradually diminishing rate. The rate of increase of temperature with descent into the crust has continuously diminished with the flow of time, and this must have had its influence on the temperature of springs, which furnish an important contribution to river water. The significance of this consideration may be judged from the composition of the water of geysers. Thus Geyser, in Iceland, contains 884 parts of sodium per million, or nearly 160 times as much as Sir John Murray estimates is present in average river water. A mean of the analyses of six geysers in different parts of the world gives 400 parts of sodium per million, existing partly as chloride, but also as sulphate and carbonate.

It should not be overlooked that the present is a calm and quiet epoch in the earth's history, following after a time of fiery activity. More than once, indeed, has the past been distinguished by unusual manifestations of volcanic energy, and these must have had some effect upon the supply of sodium to the ocean. Finally, although the existing ocean water has apparently but slight effect in corroding the rocks which form its bed, yet it certainly was not inert when its temperature was not far removed from the critical point. Water begins to exert a powerful destructive action on silicates at a temperature of 180° C., and during the interval occupied in cooling from 370 to 180° C. a considerable quantity of sodium may have entered into solution.

A review of the facts before us seems to render some reduction in Dr. Joly's estimate imperative. A precise assessment is impossible, but I should be inclined myself to take off some ten or thirty millions of years.

We may next take the evidence of the stratified rocks. Their total maximum thickness is, as we have seen, 265,000 feet, and consequently if they accumulated at the rate of one foot in a century, as evidence seems to suggest, more than twenty-six millions of years must have elapsed during their formation.

### *Obscure Chapter in the Earth's History.*

Before discussing the validity of the argument on which this last result depends, let us consider how far it harmonises with previous ones. It is consistent with Lord Kelvin's and Professor Darwin's, but how does it accord with Professor Joly's? Supposing we reduce his estimate to fifty-five millions; what was the earth doing during the interval between the period of fifty-five millions of years ago and that of only 26½ millions of years ago, when, it is presumed, sedimentary rocks commenced to be formed? Hitherto we have been able to reason on probabilities; now we enter the dreary region of possibilities, and open that obscure chapter in the history of the earth previously hinted at. For there are many possible answers to this question. In the first place the evidence of the stratified rocks may have been wrongly interpreted, and two or three times the amount of time we have demanded may have been consumed in their formation. This is a very obvious possibility, yet again our estimate concerning these rocks may be correct, but we may have erroneously omitted to take into account certain portions of the Archæan complex, which may represent primitive sedimentary rocks, formed under exceptional conditions, and subsequently transformed under the influence of the internal heat of the earth. This, I think, would be Prof. Bonney's view. Finally Lord Kelvin has argued that the life of the sun as a luminous star is even more briefly limited than that of our oceans. In such a case if our oceans were formed fifty-five millions of years ago, it is possible that after a short existence as almost boiling water they grew colder and colder, till they became covered with thick ice, and moved only in obedience to the tides. The earth, frozen and dark, except for the red glow of her volcanoes, waited the coming of the sun, and it was not till his growing splendour had banished the long night that the cheerful sound of running waters was heard again in our midst. Then the work of denudation and deposition seriously recommenced, not to cease till the life of the sun is spent. Thus the thickness of the stratified series may be a measure rather of the duration of sunlight than of the period which has elapsed since the first formation of the ocean. It may have been so—we cannot tell—but it may be fairly urged that we know less of the origin, history, and constitution of the sun than of the earth itself, and that, for aught we can say to the contrary, the sun may have been shining on the just-formed ocean as cheerfully as he shines to-day.

### *Time required for the Evolution of the Living World.*

But, it will be asked, how far does a period of twenty-six millions satisfy the demands of biology? Speaking only for myself, although I am aware that eminent biologists are not wanting who share this opinion, I answer, Amply. But it will be exclaimed, Surely there are "comparisons in things." Look at Egypt, where more than 4,000 years since the same species of man and animals lived and flourished as to-day. Examine the frescoes and study the living procession of familiar forms they so faithfully portray, and then tell us, how comes it about that from changes so slow as to be inappreciable in the lapse of forty centuries you propose to build up the whole organic world in the course of a mere twenty-six millions of years? To all which we might reply that even changeless Egypt presents us with at least one change—the features of the ruling race are to-day not quite the same as those of the Pharaohs. But putting this on one side, the admitted constancy in some few common forms proves very little, for so long as the environment remains the same natural selection will conserve the type, and, so far as we are able to judge, conditions in Egypt have remained remarkably constant for a long period.

Change the conditions, and the resulting modification of the species becomes manifest enough; and in this connection it is only necessary to recall the remarkable mutations observed and recorded by Prof. Weldon in the case of the crabs in Plymouth Harbour. In response to increasing turbidity of the sea water these crabs have undergone or are undergoing a change in the relative dimensions of the carapace, which is persistent, in one direction, and rapid enough to be determined by measurements made at intervals of a few years.

Again, animals do not all change their characters at the same rate: some are stable, in spite of changing conditions, and these have been cited to prove that none of the periods we look upon as probable, not twenty-five, not a hundred millions of years, scarce any period short of eternity, is sufficient to account for the evolution of the living world. If the little tongue-shell, *Lingula*, has endured with next to no perceptible change from the Cambrian down to the present day, how long, it is sometimes inquired, would it require for the evolution of the rest of the animal kingdom? The reply is simple: the cases are dissimilar, and the same record which assures us of the persistency of the *Lingula* tells us in language equally emphatic of the course of evolution which has led from the lower organisms upwards to man. In recent and Pleistocene deposits the relics of man are plentiful: in the latest Pliocene they have disappeared, and we encounter the remarkable form *Pithecanthropus*; as we descend into the Tertiary systems the higher mammals are met with, always sinking lower and lower in the scale of organisation as they occur deeper in the series, till in the Mesozoic deposits they have entirely disappeared, and their place is taken by the lower mammals, a feeble folk, offering little promise of the future they were to inherit. Still lower, and even these are gone; and in the Permian we encounter reptiles and the ancestors of reptiles, probably ancestors of mammals too; then into the Carboniferous, where we find amphibians, but no true reptiles; and next into the Devonian, where fish predominate, after making their earliest appearance at the close of the Silurian times; thence downwards, and the vertebrata are no more found—we trace the evolution of the invertebrata alone. Thus the orderly procession of organic forms follows in precisely the true phylogenetic sequence; invertebrata first, then vertebrates, at first fish, then amphibia, next reptiles, soon after mammals, of the lowlier kinds first, of the higher later, and these in increasing complexity of structure till we finally arrive at man himself. While the living world was thus unfolding into new and nobler forms, the immutable *Lingula* simply perpetuated its kind. To select it, or other species equally sluggish, as the sole measure of the rate of biologic change would seem as strange a proceeding as to confound the swiftness of a river with the stagnation of the pools that lie beside its banks. It is occasionally objected that the story we have drawn from the palæontological record is mere myth or is founded only on negative evidence. Cavils of this kind prove a double misapprehension, partly as to the facts, partly as to the value of negative evidence, which may be as good in its way as any other kind of evidence.

Geologists are not unaware of the pitfalls which beset negative evidence, and they do not conclude from the absence of fossils in the rocks which underlie the Cambrian that pre-Cambrian periods were devoid of life; on the contrary, they are fully persuaded that the seas of those times were teeming with a rich variety of invertebrate forms. How is it that, with the exception of some few species found in beds immediately underlying the Cambrian, these have left behind no vestige of their existence? The explanation does not lie in the nature of the sediments, which are not unfitted for the preservation of fossils, nor in the composition of the then existing sea water, which may have contained quite as much calcium carbonate as occurs in our present oceans; and the only plausible supposition would appear to be that the organisms of that time had not passed beyond the stage now represented by the larvæ of existing invertebrata, and consequently were either unprovided with skeletons, or at all events with skeletons durable enough for preservation. If so, the history of the earlier stages of the evolution of the invertebrata will receive no light from palæontology; and no direct answer can be expected to the question whether, eighteen or nineteen millions of years being taken as sufficient for the evolution of the vertebrata, the remaining available eight millions would provide for that of the invertebrate classes which are represented in the lowest Cambrian deposits. On *a priori* grounds there would appear to be no reason why it should not. If two millions of years afforded time enough for the conversion of fish into amphibians, a similar period should suffice for the evolution of trilobites from annelids, or of annelids from trochospheres. The step from gastrulas to trochospheres might be accomplished in another two millions, and two millions more would take us from gastrulas through morulas to protozoa.

As things stand, biologists can have nothing to say either for or against such a conclusion: they are not at present in a position to offer independent evidence; nor can they hope to be so until they have vastly extended those promising investigations which they are only now beginning to make into the rate of the variation of species.

### *Unexpected Absence of Thermal Metamorphosis in Ancient Rocks.*

Two difficulties now remain for discussion: one based on theories of mountain chains, the other on the unaltered state of some ancient sediments. The latter may be taken first. Prof. van Hise writes as follows regarding the pre-Cambrian rocks of the Lake Superior district: "The Penokee series furnishes an instructive lesson as to the depth to which rocks may be buried and yet remain but slightly affected by metamorphosis. The series itself is 14,000 feet thick. It was covered before being upturned with a great thickness of Keweenaw rock. This series at the Montreal River is estimated to be 50,000 feet thick. Adding to this the known thickness of the Penokee series, we have a thickness of 64,000 feet. . . . The Penokee rocks were then buried to a great depth, the exact amount depending upon their horizon and upon the stage in Keweenaw time, when the tilting and erosion, which brought them to the surface, commenced.

"That the synclinal trough of Lake Superior began to form before the end of the Keweenaw period, and consequently that the Penokee rocks were not buried under the full succession, is more than probable. However, they must have been buried to a great depth—at least several miles—and thus subjected to high pressure and temperature, notwithstanding which they are comparatively unaltered" (*Tenth Annual Report U.S. Geol. Survey*, 1888–89, p. 457).

I select this example because it is one of the best instances of a difficulty that occurs more than once in considering the history of sedimentary rocks. On the supposition that the rate of increment of temperature with descent is 1° F. for every 84 feet, or 1° C. for every 150 feet, and that it was no greater during these early Penokee times, then at a depth of 50,000 feet the Penokee rocks would attain a temperature of nearly 333° C.; and since water begins to exert powerful chemical action at 180° C. they should, on the theory of a solid cooling globe, have suffered a metamorphosis sufficient to obscure their resemblance to sedimentary rocks. Either then the accepted rate of downward increase of temperature is erroneous, or the Penokee rocks were never depressed, in the place where they are exposed to observation, to a depth of 50,000 feet. Let us consider each alternative, and in the first place let us apply the rate of temperature increment determined by Prof. Agassiz in this very Lake Superior district: it is 1° C. for every 402 feet, and twenty-five millions of years ago, or about the time when we may suppose the Penokee rocks were being formed, it would be 1° C. for every 305·5 feet, with a resulting temperature at a depth of 50,000 feet of 163° C. only. Thus the admission of a very low rate of temperature increment would meet the difficulty; but on the other hand it would involve a period of several hundreds of millions of years for the age of the "consistentior status," and thus greatly exceed Prof. Joly's maximum estimate of the age of the oceans. We may therefore turn to the second alternative. As regards this it is by no means certain that the exposed portion of the Penokee series ever was depressed 50,000 feet: the beds lie in a synclinal the base of which indeed may have sunk to this extent, and entered a region of metamorphosis; but the only part of the system that lies exposed to view is the upturned margin of the synclinal, and as to this it would seem impossible to make any positive assertion as to the depth to which it may or may not have been depressed. To keep an open mind on the question seems our only course for the present, but difficulties like this offer a promising field for investigation.

### *The Formation of Mountain Ranges.*

It is frequently alleged that mountain chains cannot be explained on the hypothesis of a solid earth cooling under the conditions and for the period we have supposed. This is a question well worthy of consideration, and we may first endeavour to picture to ourselves the conditions under which mountain chains arise. The floor of the ocean lies at an average depth of 2000 fathoms below the land, and is maintained at a constant temperature, closely approaching 0° C., by the passage over it of cold water creeping from the polar regions. The average temperature of the surface of the land is above zero, but we can afford to disregard the difference in temperature between it and the ocean floor, and may take them both at zero. Consider next the increase of temperature with descent, which occurs beneath the continents: at a depth of 13,000 feet, or at same depth as the ocean floor, a temperature of 87° C. will be reached on the supposition that the rate of increase is 1° C. for 150 feet, while with the usually accepted rate of 1° C. for 108 feet it would be 120° C. But at this depth the ocean floor, which is on the same spherical surface, is at 0° C. Thus surfaces of equal temperature within the earth's crust will not be spherical, but will rise or fall beneath an imaginary spherical or spheroidal surface according as they occur beneath the continents or the oceans. No doubt at some depth within the earth the departure of isothermal surfaces from a spheroidal form will disappear; but considering the great breadth both of continents ond oceans this depth must be considerable, possibly even forty or fifty miles. Thus the sub-continental excess of temperature may make itself felt in regions where the rocks still retain a high temperature, and are probably not far removed from the critical fusion point. The effect will be to render the continents mobile as regards the ocean floor; or, *vice-versâ*, the ocean floor will be stable compared with the continental masses. Next it may be observed that the continents pass into the bed of the ocean by a somewhat rapid flexure, and that it is over this area of flexure that the sediments denuded from the land are deposited. Under its load of sediment the sea-floor sinks down, subsiding slowly, at about the same rate as the thickness of sediment increases; and, whether as a consequence or a cause, or both, the flexure marking the boundary of land and sea becomes more pronounced. A compensating movement occurs within the earth's crust, and solid material may flow from under the subsiding area in the direction of least resistance, possibly towards the land. At length, when some thirty or forty thousand feet of sediment have accumulated in a basin-like form, or, according to our reckoning, after the lapse of three or four millions of years, the downward movement ceases, and the mass of sediment is subjected to powerful lateral compression, which, bringing its borders into closer proximity by some ten or thirty miles, causes it to rise in great folds high into the air as a mountain chain.

It is this last phase in the history of mountain making which has given geologists more cause for painful thought than probably any other branch of their subject, not excluding even the age of the earth. It was at first imagined that during the flow of time the interior of the earth lost so much heat, and suffered so much contraction in consequence, that the exterior, in adapting itself to the shrunken body, was compelled to fit it like a wrinkled garment. This theory, indeed, enjoyed a happy existence till it fell into the hands of mathematicians, when it fared very badly, and now lies in a pitiable condition neglected of its friends.[1]

For it seemed proved to demonstration that the contraction consequent on cooling was wholly, even ridiculously, inadequate to explain the wrinkling. But when we summon up courage to inquire into the data on which the mathematical arguments are based, we find that they include several assumptions, the truth of which is by no means self-evident. Thus it has been assumed that the rate at which the fusion point rises with increased pressure is constant, and follows the same law as is deduced from experiments made under such pressures as we can command in our laboratories down to the very centre of the earth, where the pressures are of an altogether different order of magnitude; so with a still more important coefficient, that of expansion, our knowledge of this quantity is founded on the behaviour of rocks heated under ordinary atmospheric pressure, and it is assumed that the same coefficient as is thus obtained may be safely applied to material which is kept solid, possibly near the critical point, under the tremendous pressure of the depths of the crust. To this last assumption we owe the terrible bogies that have been conjured out of "the level of no strain." The depth of this as calculated by the Rev. O. Fisher is so trifling that it would be passed through by all very deep mines. Mr. C. Davison, however, has shown that it will lie considerably deeper, if the known increase of the coefficient of expansion with rise of temperature be taken into account. It is possible, it is even likely, that the coefficient of expansion becomes vastly greater when regions are entered where the rocks are compelled into the solid state by pressure. So little do we actually know of the behaviour of rock under these conditions that the geologist would seem to be left very much to his own devices; but it would seem there is one temptation he must resist—he may not take refuge in the hypothesis of a liquid interior.

We shall boldly assume that the contraction at some unknown depth in the interior of the earth is sufficient to afford the explanation we seek. The course of events may then proceed as follows. The contraction of the interior of the earth, consequent on its loss of heat, causes the crust to fall upon it in folds, which rise over the continents and sink under the oceans, and the flexure of the area of sedimentation is partly a consequence of this folding, partly of overloading. By the time a depression of some 30,000 or 40,000 feet has occurred along the ocean border the relation between continents and oceans has become unstable, and readjustment takes place, probably by a giving way of the continents, and chiefly along the zone of greatest weakness, *i.e.* the area of sedimentation, which thus becomes the zone of mountain building. It may be observed that at great depths readjustment will be produced by a slow flowing of solid rock, and it is only comparatively near the surface, five or ten miles at the most below, that failure of support can lead to sudden fracture and collapse; hence the comparatively superficial origin of earthquakes.

---

[1] With some exceptions, notably Mr. C. Davison, a consistent supporter of the theory of contraction.

Given a sufficiently large coefficient of expansion—and there is much to suggest its existence (*vide*, p. 483)—and all the phenomena of mountain ranges become explicable: they begin to present an appearance that invites mathematical treatment; they inspire us with the hope that from a knowledge of the height and dimensions of a continent and its relations to the bordering ocean we may be able to predict when and where a mountain chain should arise, and the theory which explains them promises to guide us to an interpretation of those world-wide unconformities which Suess can only account for by a transgression of the sea. Finally it relieves us of the difficulty presented by mountain formation in regard to the estimated duration of geological time.

### *Influence of Variations in the Eccentricity of the Earth's Orbit.*

This may perhaps be the place to notice a highly interesting speculation which we owe to Prof. Blytt, who has attempted to establish a connection between periods of readjustment of the earth's crust and variations in the eccentricity of the earth's orbit. Without entering into any discussion of Prof. Blytt's methods, we may offer a comparison of his results with those that follow from our rough estimate of one foot of sediment accumulated in a century.

*Table showing the Time that has elapsed since the Beginning of the Systems in the first column, as reckoned from Thickness of Sediment in the second column, and by Prof. Blytt in the third:—*

| | Years | Years |
|---|---|---|
| Eocene | 4,200,000 | 3,250,000 |
| Oligocene | 3,000,000 | 1,810,000 |
| Miocene | 1,800,000 | 1,160,000 |
| Pliocene | 900,000 | 700,000 |
| Pleistocene | 400,000 | 350,000 |

It is now time to return to the task, too long postponed, of discussing the data from which we have been led to conclude that a probable rate at which sediments have accumulated in places where they attain their maximum thickness is one foot per century.

### *Rate of Deposition of Sediment.*

We owe to Sir Archibald Geikie a most instructive method of estimating the existing rate at which our continents and islands are being washed into the sea by the action of rain and rivers; by this we find that the present land surface is being reduced in height to the extent on an average of 1/2400 foot yearly (according to Prof. Penck 1/3600 foot). If the material removed from the land were uniformly distributed over an area equal to that from which it had been derived, it would form a layer of rock 1/2400 foot thick yearly, *i.e.* the rates of denudation and deposition would be identical. But the two areas, that of denudation and that of deposition, are seldom or never equal, the latter as a rule being much the smaller. Thus the area of that part of North America which drains into the Gulf of Mexico measures 1,800,000 square miles; the area over which its sediments are deposited is, so far as I can gather from Prof. Agassiz' statements, less than 180,000 square miles; while Mr. McGee estimates it at only 100,000 square miles. Using the largest number, the area of deposition is found to measure one-tenth the area of denudation; the average rate of deposition will therefore be ten times as great as the rate of denudation, or $\frac{1}{240}$ foot may be supposed to be uniformly distributed over the area of sedimentation in the course of a year. But the thickness by which we have measured the strata of our geological systems is not an average but a maximum thickness; we have therefore to obtain an estimate of the maximum rate of deposition. If we assume the deposited sediments to be arranged somewhat after the fashion of a wedge with the thin end seawards, then twice the average would give us the maximum rate of deposition; this would be one foot in 120 years. But the sheets of deposited sediment are not merely thicker towards the land, thinner towards the sea, they also increase in thickness towards the rivers in which they have their source, so that a very obtuse-angled cone, or, better, the down-turned bowl of a spoon, would more nearly represent their form. This form tends to disappear under the action of waves and currents, but a limit is set to this disturbing influence by the subsidence which marks the region opposite the mouth of a large river. By this the strata are gradually let downwards, so that they come to assume the form of the bowl of a spoon turned upwards. Thus a further correction is necessary if we are to arrive at a fair estimate of the maximum rate of deposition. Considering the very rapid rate at which our ancient systems diminish in thickness when traced in all directions from the localities where they attain their maximum, it would appear that this correction must be a large one. If we reduce our already corrected estimate by one-fifth, we arrive at a rate of one foot of sediment deposited in a century.

No doubt this value is often exceeded; thus in the case of the Mississippi River the bar of the south-west pass advanced between the years 1838 and 1874 a distance of over 2 miles, covering an area 2·2 miles in width with a deposit of sediment 80 feet in thickness; outside the bar, where the sea is 250 feet in depth, sediment accumulates, according to Messrs. Humphreys and Abbot, at a rate of 2 feet yearly. It is quite possible, indeed it is very likely, that some of our ancient strata have been formed with corresponding rapidity. No gravel or coarse sand is deposited over the Mississippi delta; such material is not carried further seawards than New Orleans. Thus the vast sheets of conglomerate and sandstone which contribute so largely to some of our ancient systems, such as the Cambrian, Old Red Sandstone, Millstone Grit, and Coal Measures, must have accumulated under very different conditions, conditions for which it is not easy to find a parallel; but in any case these deposits afford evidence of very rapid accumulation.

These considerations will not tempt us, however, to modify our estimate of one foot in a century; for though in some cases this rate may have been exceeded, in others it may not have been nearly attained.

Closely connected with the rate of deposition is that of the changing level of land and sea; in some cases, as in the Wealden delta, subsidence and deposition appear to have proceeded with equal steps, so that we might regard them as transposable terms. It would therefore prove of great assistance if we could determine the average rate at which movements of the ground are proceeding; it might naturally be expected that the accurate records kept by tidal gauges in various parts of the world would afford us some information on this subject; and no doubt they would, were it not for the singular misbehaviour of the sea, which does not maintain a constant level, its fluctuations being due, according to Prof. Darwin, to the irregular melting of ice in the polar regions. Of more immediate application are the results of Herr L. Holmström's observations in Scandinavia, which prove an average rise of the peninsula at the rate of 3 feet in a century to be still in progress; and Mr. G. K. Gilbert's measurements in the great Lake district of North America, which indicate a tilting of the continent at the rate of 3 inches per hundred miles per century. But while measurements like these may furnish us with some notion of the sort of speed of these changes, they are not sufficient even to suggest an average; for this we must be content to wait till sufficient tidal observations have accumulated, and the disturbing effect of the inconstancy of the sea-level is eliminated.

It may be objected that in framing our estimate we have taken into account mechanical sediments only, and ignored others of equal importance, such as limestone and coal. With regard to limestone, its thickness in regions where systems attain their maximum may be taken as negligible; nor is the formation of limestone necessarily a slow process. The successful experiments of Dr. Allan, cited by Darwin, prove that reef-building corals may grow at the astonishing rate of six feet in height per annum.

In respect of coal there is much to suggest that its growth was rapid. The carboniferous period well deserves its name, for never before, never since, have Carbonaceous deposits accumulated to such a remarkable thickness or over such wide areas of the earth's surface. The explanation is doubtless partly to be found in favourable climatal conditions, but also, I think, in the youthful energy of a new and overmastering type of vegetation, which then for the first time acquired the dominion of the land. If we turn to our modern peat-bogs, the only Carbonaceous growths available for comparison, we find from data given by Sir A. Geikie that a fairly average rate of increase is six feet in a century, which might perhaps correspond to one foot of coal in the same period.

The rate of deposition has been taken as uniform through the whole period of time recorded by stratified rocks; but lest it should be supposed that this involves a tacit admission of uniformity, I hasten to explain that in this matter we have no choice; we may feel convinced that the rate has varied from time to time, but in what direction, or to what extent, it is impossible to conjecture. That the sun was once much hotter is probable, but equally so that at an earlier period it was much colder; and even if in its youth all the activities of our planet were enhanced, this fact might not affect the maximum thickness of deposits. An increase in the radiation of the sun, while it would stimulate all the powers of subaërial denudation, would also produce stronger winds and marine currents; stronger currents would also result from the greater magnitude and frequency of the tides, and thus while larger quantities of sediment might be delivered into the sea they would be distributed over wider areas, and the difference between the maximum and average thickness of deposits would consequently be diminished. Indications of such a wider distribution may perhaps be recognised in the Palæozoic systems. Thus we are compelled to treat our rate of deposition as uniform, notwithstanding the serious error this may involve.

The reasonableness of our estimate will perhaps best appear from a few applications. Fig. 2 is a chart, based on a map by De Lapparent, representing the distribution of land and sea over the European area during the Cambrian period. The strata of this system attain their maximum thickness of 12,000 feet in Merionethshire, Wales; they rapidly thin out northwards, and are absent in Anglesey; scarcely less rapidly towards Shropshire, where they are 3000 feet thick; still a little less rapidly towards the Malverns, where they are only 800 feet thick; and most slowly towards St. David's Head, where they are 7400 feet thick. The Cambrian rocks of Wales were in all probability the deposits of a river system which drained some vanished land once situated to the west. How great was the extent of this land none can say; some geologists imagine it to have obliterated the whole or greater part of the North Atlantic Ocean. For my part I am content with a somewhat large island. What area of this island, we may ask, would suffice to supply the Cambrian sediments of Wales and Shropshire? Admitting that the area of denudation was ten times as large as the area of deposition, its dimensions are indicated by the figure *a b c d* on the chart. This evidently leaves room enough on the island to furnish all the other deposits which are distributed along the western shores of the Cambrian Sea, while those on the east are amply provided for by that portion of the European continent which then stood above water.

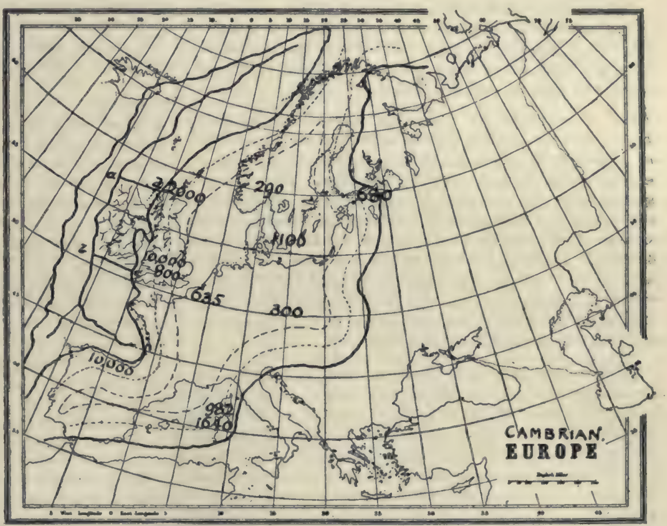

FIG. 2.—Chart of the distribution of land and sea, and of the thickness of deposits of the Cambrian system. The dotted lines indicate distances of 100 and 200 miles from the shore.

If one foot in a century be a quantity so small as to disappoint the imagination of its accustomed exercise, let us turn to the Cambrian succession of Scandinavia, where all the zones recognised in the British series are represented by a column of sediment 290 feet in thickness. If 1,600,000 years be a correct estimate of the duration of Cambrian time, then each foot of the Scandinavian strata must have occupied 5513 years in its formation. Are these figures sufficiently inconceivable?

In the succeeding system, that of the Ordovician, the maximum thickness is 17,000 feet. Its deposits are distributed over a wider area than the Cambrian, but they also occupied longer time in their formation; hence the area from which they were derived need not necessarily have been larger than that of the preceding period.

Great changes in the geography of our area ushered in the Silurian system: its maximum thickness is found over the Lake district, and amounts to 15,000 feet; but in the little island of Gothland, where all the subdivisions of the system, from the Landovery to the Upper Ludlow, occur in complete sequence, the thickness is only 208 feet. In Gothland, therefore, according to our computation, the rate of accumulation was one foot in 7211 years.

With this example we must conclude, merely adding that the same story is told by other systems and other countries, and that, so far as my investigations have extended, I can find no evidence which would suggest an extension of the estimate I have proposed. It is but an estimate, and those who have made acquaintance with "estimates" in the practical affairs of life know how far this kind of computation may guide us to or from the truth.

This Address is already unduly long, and yet not long enough for the magnitude of the subject of which it treats. As we glance backwards over the past we see catastrophism yield to uniformitarianism, and this to evolution, but each as it disappears leaves behind some precious residue of truth. For the future of our science our ambition is that which inspired the closing words of your last President's Address, that it may become more experimental and exact. Our present watchword is Evolution. May our next be Measurement and Experiment, Experiment and Measurement.

## NOTES.

ANOTHER of those disastrous hurricanes which occasionally visit the West Indies and United States at this season of the year has to be recorded. On the 8th inst. a storm of great violence struck the coasts of Louisiana and Texas, and, owing to the thickly populated districts over which it swept and to the high water wave which accompanied it, immense destruction to property and lamentable loss of life ensued. The fury of the storm is said to have been felt for at least a hundred miles inland, but up to the present time scarcely any details have arrived as to its character and the exact path that it followed. This part of America is one of the three regions referred to in the works of Prof. W. M. Davis from which tropical storms move into temperate latitudes in the northern hemisphere; but we must wait for further details before it can be stated whether the one in question was of the nature of a tornado, which differs from an ordinary hurricane chiefly in its excessive violence over a small, instead of a large, area. From the description so far given, and from its duration, the storm would appear to have been of the nature of the worst West India hurricanes.

THE *Stella Polare*, with the Duke of the Abruzzi and members of his Arctic expedition on board, arrived at Christiania on Tuesday. A Reuter telegram from Tromsö states that the ship was pushed by the ice in Table Bay right on to the land, and four separate parties were sent out from it. The first was despatched northwards to establish depôts, and had to travel two days overland. The second party, consisting of a Norwegian and two Italians, was to have been out twelve days, but the men never returned. The third party were away twenty-four days, and the fourth 105 days. This last reached lat. 86° 33′ N., thus penetrating a little further north than Dr. Nansen and Lieut. Johansen, who reached lat. 86° 14′ N. The scientific results of the expedition are said to be satisfactory, but no information concerning them, or of the latitude observations, is yet available.

THE recent Congress of British Chambers of Commerce at Paris adopted resolutions urging the adoption of the metric system of weights and measures in our Government departments, and the teaching of decimals in public elementary schools at an early stage, as an essential part of arithmetic.

THE *Entomologist* for September contains an interesting account of the artificial ant-hills in the Paris Exhibition. These are shown by M. C. Janet, who has devoted many years to studying the habits of the social Hymenoptera. They are made of porous pink plaster covered with glass, through which visitors may observe the movements of their busy inhabitants, and are constructed after the plan of a natural hill in a garden near Beauvois. Several species of ants are exhibited, one of which has "slaves." M. Janet is of opinion that ants have a language of sounds, and that at any rate they produce grating noises, probably by rubbing together their bodies; while he is fully assured that they possess an acute sense of hearing.

To the current issue of the *Entomologist's Monthly Magazine*, Sir George Hampson communicates a notice of certain malformed specimens of moths recently acquired by the British Museum. The object of the communication is to draw attention, not only to peculiarities of the insects themselves, but likewise to the fact that the authorities of the Museum have recently started a collection to display the abnormalities and "sports" which occur among insects, and, it may be added, among all other groups of animals as well. Sir George Hampson appeals to all entomologists to assist in the formation of this series.

THE chapters on "Nature and Science for Young Folks" in the August and September numbers of *St. Nicholas* maintain, under the able editorship of Mr. E. F. Bigelow, their high standard of excellence and interest, many of the illustrations being unusually attractive and instructive. In the August number we have first a delightful dissertation on "Flowers of the Sea," with an exquisite photograph of a dried sea-weed; this being followed by an account of the manner in which gnat-larvæ maintain their breathing apparatus at the surface of the water during the process of respiration. In the September issue the attention of the young reader is at first attracted to the intrinsic beauty of leaves—such as can be met with in any copse or wood—by an account of how to make leaf-garlands and chains, from which the transition is easy to the numerous points of interest displayed by microscopic sections of these beautiful structures, and to the part they play in the economy of nature. A prize competition in which figures of birds and insects are given for identification by the reader strikes us as an especially good feature, and in every way superior to the useless and hackneyed "missing word competition."

THE meteorological reporter to the Government of India has issued his usual "Brief memorandum on the weather in India during the months of June and July, and forecast of the general distribution of the rainfall in India during the months of August and September, 1900." The character of the monsoon rains in June and July has been in fair accordance with the forecast issued in the beginning of June. From a consideration of the weather and of the snowfall in the mountains during those months, it is assumed that the general distribution of rainfall for the months of August and September, will be favourable. A comparison with several previous years also suggests that it is probable that the rainfall of the retreating south-west monsoon (October to December) will be favourably distributed in the Peninsula.

THE French Meteorological Office has recently issued its *Annales* for the year 1897; the first volume, under the title of "Memoirs," contains, in addition to the usual articles relating to thunderstorms and magnetic observations, a discussion by M. Angot of the temperature at a number of stations since 1851. This valuable paper forms the first part of an investigation of the climate of France during forty years ending with 1890. A second memoir by M. Angot contains the principal results of the simultaneous observations made at the Meteorological Office in Paris and on the Eiffel Tower during six years. M. Teisserenc de Bort, who established and maintains at Trappes an observatory specially devoted to the study of clouds and the movements of the upper air, publishes the results hitherto obtained from numerous ascents of unmanned balloons. The second volume contains the results of observations at stations in France and its Colonies. The publication of the valuable series of rainfall observations, which has hitherto formed the third volume, is postponed for the present, from motives of economy. The Central Office in Paris receives 167 telegraphic reports daily, and in the year in question 89 per cent. of the weather forecasts were successful. The observers receive encouragement in the way of medals, sixty-eight of these were awarded for observations on land, and eighteen for observations at sea. Much attention is now given to the development of observations in the French Colonies, and in distant parts generally, a matter which, until a few years ago, had been somewhat overlooked.

MANY attempts have been made to introduce Euclid's Fifth Book, or its equivalent, in the teaching of geometry, and recently a work on the Fifth and Sixth Books appeared from the pen of Prof. M. J. M. Hill, F.R.S. A later contribution to this subject is a paper, by Prof. George A. Gibson, on "Proportion," a substitute for the Fifth Book of Euclid's Elements, published as an appendix to the *Proceedings* of the Edinburgh Mathematical Society. A deductive treatment of proportion such as this, which takes account of incommensurability, is doubtless a good mental training for the advanced student; but seeing that in an elementary course on arithmetic and algebra the rules for multiplying and dividing negative and fractional quantities are practically never logically proved by students, but rather assumed and applied to working examples, there is surely sufficient precedent for taking it as granted that the laws of proportion apply to incommensurable magnitudes. At any rate the matter is one for discussion between the two schools, one of which seeks to put the teaching of mathematics on a rigorously deductive basis, while the other would abolish Euclid's lengthy deductions and rather teach the results of mathematical reasoning and how to work with them in practical applications.

WE have received a copy of a rectorial address, delivered by Prof. Brückner before the University of Berne, entitled "Die Schweizerische Landschaft einst und jetzt." The topographical changes which have taken place in Switzerland since the glacial period and within historic times are summarised, and apart from the intrinsic interest of the subject, the address is an admirable illustration of the methods of descriptive geography.

DR. A. LORENZEN contributes two articles to *Die Natur* on the Danish Expedition to East Greenland in 1898–1899. The expedition was successful in closely following the plan of work with which it set out. Its chief results consist of mapping the coast of Greenland from lat. 65° ¾′ N. to 67° 22′ N., and sketching it as far as 68° N.; making botanical, zoological and geological collections; ethnographic observations; observations of the ice north of the Angmagsalik district; meteorological and other observations in winter quarters.

OUR German contemporary, *Naturwissenschaftliche Wochenschrift* for August 19 and September 2 contains a full account of the discovery of the remains of *Grypotherium listai* in Ultima Esperanza cavern, Patagonia.

Perhaps the most interesting article in the September number of the *Irish Naturalist* is an account, by Mr. R. Warren, of a visit to Loch Erne in search of the Sandwich tern, which has hitherto been known to breed in Ireland only in a single locality in county Mayo.

THE report of the expeditions organised by the British Astronomical Association to observe the total solar eclipse of May 28, 1900, will be contained in a volume shortly to be issued from the office of *Knowledge*. The work will be edited by Mr. E. Walter Maunder, and will contain many photographs of the various stages of the eclipse.

AMONG the scientific instrument makers who exhibited in the British Section at the Paris Exhibition, the Grand Prix was awarded to four firms, namely:—Class 15 (*Instruments de Précision*), the Cambridge Scientific Instrument Co., Ltd., Cambridge, and Messrs. Ross, Ltd., London. Class 16 (*Médécine et Chirurgie*), Messrs. Down Bros., London. Class 27 (*Applications diverses de l'Électricité*), Mr. James White, Glasgow. Mr. W. Duddell received a gold medal (Class 27) for the oscillograph exhibited by the Cambridge Scientific Instrument Company, and Mr. Wayne, the inventor of both the Wayne and Simplex Steam-engine Indicators, and now engaged at the Cambridge works, received a silver medal. A silver medal was also awarded in Class 16 to the company itself. Two gold and two silver medals were awarded to Mr. J. J. Hicks, and one to Messrs. Crompton and Co., Messrs. Negretti and Zambra, and Messrs. Watson and Sons; and silver medals were also awarded to Mr. A. Higgins, Mr. E. Wellings, Mr. W. Sims and Mr. W. Barton of Mr. Hicks' firm.

THE additions to the Zoological Society's Gardens during the past week include a Lion (*Felis leo*) from Uganda, presented by Captain Delme Radcliff; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss K. Bishop; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. G. Percy Ashmore; two Cunning Bassaris (*Bassaris astuta*) from Mexico, presented by Miss Franklin; two Chilian Sea Eagles (*Geranoaëtus melanoleucus*) from South America, presented by Mr. Tom Simonds; a Puma (*Felis concolor*) from the Argentine Republic, presented by Mr. Maurice F. Dennis; a Nilotic Crocodile (*Crocodilus niloticus*) from Omdurman, presented by Major H. B. Weatherall; two Tenrecs (*Centetes ecaudatus*) from Madagascar, a Cunning Bassaris (*Bassaris astuta*) from Mexico, three Cardinal Eclectus (*Eclectus cardinalis*) from Moluccas, deposited; two Purple Herons (*Ardea purpurea*), two Common Cormorants (*Phalaerocorax carbo*), three Common Spoonbills (*Platalea leucorodia*), European, purchased.

## OUR ASTRONOMICAL COLUMN

EPHEMERIS FOR OBSERVATIONS OF EROS.—The following is continued from the new data given by E. Millosevich in the *Astronomische Nachrichten* (Band 153, No. 3660):—

*Ephemeris for 12h. Berlin Mean Time.*

| 1900. | R.A. h. m. s. | Decl. ° ′ ″ |
|---|---|---|
| Sept. 13 | 2 34 19·43 | +38 7 24·2 |
| 14 | 35 11·87 | 38 30 7·3 |
| 15 | 36 2·36 | 38 52 52·9 |
| 16 | 36 50·83 | 39 15 40·7 |
| 17 | 37 37·20 | 39 38 30·3 |
| 18 | 38 21·38 | 40 1 21·4 |
| 19 | 39 3·30 | 40 24 13·9 |
| 20 | 2 39 42·89 | +40 47 7·2 |

The following elements for two epochs some two years apart are also given in the same periodical:—

I. Epoch 1898 August 2·5
Berlin.

$$\begin{array}{l} M = 205^\circ\ 21'\ 41''\cdot83 \\ \left.\begin{array}{l} \pi = 121\ 10\ 51\cdot40 \\ \Omega = 303\ 31\ 56\cdot17 \\ i = 10\ 49\ 35\cdot35 \end{array}\right\} 1900\cdot0 \\ \phi = 12\ 52\ 14\cdot44 \\ \mu = 2015''\cdot26908 \\ \log a = 0\cdot1637824 \end{array}$$

II. Epoch 1900 October 31·5
Berlin.

$$\begin{array}{l} M = 304^\circ\ 24'\ 40''\cdot34 \\ \left.\begin{array}{l} \pi = 121\ 9\ 47\cdot82 \\ \Omega = 303\ 30\ 50\cdot02 \\ i = 10\ 49\ 38\cdot97 \end{array}\right\} 1900\cdot0 \\ \phi = 12\ 52\ 40\cdot61 \\ \mu = 2015''\cdot23324 \\ \log a = 0\cdot1637875 \end{array}$$

## THE DAYLIGHT METEOR OF SUNDAY, SEPTEMBER 2.

JUST before sunset on September 2 a magnificent meteor was observed in the north of England and Scotland. A large number of descriptions of the object have appeared in the newspapers, and it appears that notwithstanding broad daylight the spectacle was a very brilliant one.

At St. Anne's, Lancashire, the meteor fell in a northerly direction, and left a column of white smoke, which remained visible ten minutes. At Hunt's Cross the time was noted as 6h. 52m., and the object is said to have fallen near Halewood, leaving a long trail of white dust for several minutes. As seen from Birkenhead the meteor appeared at 6h. 54m. in the N.E., and looked like a descending rocket. Its path was nearly vertical, and it left a "dust trail" for nearly six minutes. At Wetherby, Yorks, the smoke-like cloud left by the nucleus remained visible until 7h. 30m. At Overton, Ellesmere, the object is said to have apparently fallen on a field on the left bank of the Dee, about a mile from Bangor Isycoed. At Ulverstone it passed over Morecambe Bay, in a southerly direction towards Blackpool. At Penton, Cumberland, the time was noted as 6h. 54m., and the direction was due south. It remained visible two seconds, and was falling towards the earth.

At Keswick, Mr. Lawson Dykes saw the fireball at 6h. 55m., and says it fell through an arc of about ten degrees, the altitude of appearance being 35° and disappearance 25°. It was pear-shaped and of immense size, with a distinct tail. The line of flight was almost due N. to S. At Warkton, Northamptonshire, Dr. Herbert Spencer noted the time as 6h. 55m., and says the track of the meteorite was afterwards marked by a narrow white streak, which persisted for more than five minutes.

At and near Edinburgh the fireball was witnessed by many persons. One observer says that at 6h. 55m. there was a sudden flash, and what appeared to be a streak of molten silver followed by a train of sparks whizzed past, apparently falling into a large field of turnips on his right hand. Its direction was due S.E. At Inveresk the meteor appeared to be in the direction of Dalkeith. It resembled a large ball of fire with a tail, and seemed to fall to the earth. At Earlswood, nine miles S.S.E. of Birmingham, the time was noted as 6h. 55m., and the end point of the flight occurred in altitude 20° N. and was directed from N.N.E. At Blackwall, Alfreton, an observer noted the time as 6h. 53m., and says the meteor left a trace in the sky of a sinuous form and in colour a silver-gray. The trace remained distinctly visible in the sky for thirty minutes. Its direction was N.W. At West Kirby, Birkenhead, the meteor was seen to fall into a wood on the east side of the hill there, and apparently so close that the observer thought it would possibly set fire to the trees.

In Wiltshire a party of Bathonians saw it while driving, and describe it as a ball of fire with a comet-like tail falling direct from heaven to earth and alighting apparently in a field about a mile distant.

A number of other accounts have come to hand, but for the most part they do not supply any details which would be useful for computing the real path of the fireball. It probably disappeared over Lancashire at a height of twenty-five miles, and was directed from a radiant point high in the northern sky. The long-enduring streak or cosmic cloud was no doubt illuminated by the sun's rays. It is not likely that the exact heights of appearance and disappearance of the meteor can be ascertained, though there are plenty of descriptions. The object having appeared in daylight, there were no stars or other celestial objects visible by which its path could be determined. The observers content themselves with giving rough estimations as to the general direction, but these are of little use in any endeavour to compute the real path of the object. It is hoped, however, that some further observations of a more satisfactory character will come to hand and enable a fairly trustworthy result to be obtained. The fireball was a very exceptional one to have created so brilliant an effect just before sunset.

It will be remembered that a large fireball was seen on January 9 at 2h. 55m. in the afternoon, and that on July 17 last another of these striking objects appeared soon after sunset and was observed by many persons in Scotland and the north of England. The present year is likely to be a notable one as regards the number and brilliancy of the fireballs which have appeared.

W. F. DENNING.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

THE new Technical School at Bootle will be opened by the Earl of Derby on Thursday, September 27.

AFTER a discussion upon technical and commercial education at the recent Congress of British Chambers of Commerce, in Paris, the meeting endorsed the following resolution, which was adopted at the Congress of Chambers of Commerce of the Empire in June 1900:—"That it is most desirable to take steps to urge the extension of technical and commercial education throughout the Empire, and that wherever possible this education should be placed under efficient public control; and that this congress is of opinion that the utmost effort should be made throughout the Empire to encourage and furnish facilities for commercial education as a branch of technical and scientific study, and that the Home and Colonial Governments be moved to give aid thereto and ample powers of contribution out of local resources; and, further, it is very desirable that Chambers of Commerce should be represented on Boards of Education in order to advance the interests of commercial education."

THE following is a list of candidates successful in the recent competition for the Whitworth Scholarships and Exhibitions. Scholarships of 125*l.* a year each (tenable for three years): George W. O. Howe, Harold B. Philpot, Harry Noble, William M. Wallace. Exhibitions of 50*l.* (tenable for one year): Alfred W. Steed, Charles E. Stanier, Benjamin Moss, Isaac V. Robinson, Herbert G. Tisdall, Leonard Southerns, Charles A. King, John McCulloch, William P. Chandler, Charles W. Price, Harry B. Matthews, Leonard G. Crawford, James Wilson, George Stow, Joseph H. Dobson, Alec P. Simpson, Fredk. G. Rappoport, Arthur J. Butler, Alfred L. Oke, James M. Macintosh, William H. Cumner, Thomas A. Goskar, Leopold D. Coueslant, John C. Gardner, James C. Metcalfe, Harold Shatwell, Walter A. Turnbull, John E. Grant, Albert S. Raworth, Henry H. Thorne.

THE following Royal Exhibitions, National Scholarships and Free Studentships in Science have been awarded by the Board of Education, South Kensington. Royal Exhibitions: James C. Macfarlane, William T. S. Butlin, Louis D. Stansfeld, Leonard A. V. Webb, Isaac V. Robinson, Arthur Baker, Benjamin Moss. National Scholarships for Mechanics: Albert E. Dodridge, Albert Wilson, Charles E. Stanier, Frederick Bowen, Robert R. Cormack. Free Studentships for Mechanics: Fred. G. Rappoport, Harry B. Matthews, John Alexander. National Scholarships for Physics: Ernest Nightingale, Royden C. Wale, Frederick P. Rolfe, William Tannock, Frank E. Glover. Free Studentship for Physics: Leonard R. Broome. National Scholarships for Chemistry: George H. Green, Philip S. Pomeroy, William H. Stephens, Harold Leadbetter, Frederick P. Leach. Free Studentship for Chemistry: Hamilton McCombie. National Scholarships for Biology: Charles Martin, Archibald D. Hogg, Cosby T. Nesbitt, Hamilton E. Quick, Horace A. Wager. National Scholarships for Geology: Hubert C. Jones, William Rawson. Free Studentship for Geology: Stanley R. Jones.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, September 3.—M. Maurice Lévy in the chair.—Physiological action and therapeutical applications of compressed oxygen, by M. A. Mosso. The author has verified and extended the observations of Haldane upon the simultaneous action of compressed oxygen and carbonic oxide upon various animals. Where at the ordinary pressure of the atmosphere 0·5 per cent. or less of the carbonic oxide is fatal, animals are not poisoned in an atmosphere of oxygen at two atmospheres containing 6 per cent. of the gas. This result is of interest from the physiological point of view as showing that animals may live, without red corpuscles, on the oxygen dissolved in the blood plasma, provided that the amount in solution is sufficiently increased by pressure.—The last sign of life, by M. Augustus D. Waller. Living matter responds to an electrical stimulus by a current in the same direction. The same substance, killed by heat, either gives no response or gives a polarisation current in the opposite sense. This method is applied to determine the last sign of life.—On the Laplace equations with quadratic solutions, by M. Tzitzeica.—On singularities of analytical functions, and in particular of functions defined by differential equations, by M. Paul Painlevé.—The effects of work of certain muscular groups on other groups doing no work, by MM. Kronecker and Cutter. The muscles of the lower limbs exercised in climbing were found to exert an influence upon the biceps of the arm. A moderate amount of work done by one group of muscles appears to have a strengthening effect upon another group not taking part in the action, the effect being probably due to an increase in the circulation of the blood and lymph.—On a perpetual calendar, by M. l'abbé Salvatore Franco.

THURSDAY, SEPTEMBER 20, 1900.

## *A MAGNETIC THEORY OF THE UNIVERSE.*

*From Matter to Man; a New Theory of the Universe.* By A. Redcote Dewar. Pp. 289+viii. (London: Chapman and Hall, Ltd., 1898.)

WE do not recommend this work to the serious attention of our readers, but as a study in word-stringing it is not devoid of interest. It appears to be the production of a writer who has acquired a knowledge of scientific terms by extensive reading, without having any real grasp of the vast range of subjects over which he travels. The result is such as might have been arrived at by a student who had been through a hurried course of cram, and who at his final examination had been set some such question as this:—Given, a vocabulary of scientific terms, construct a theory of the universe.

The author is strong on magnetism. We have never met with such a liberal use of this term as is indulged in by Mr. Dewar. Like the "vapours" which afflicted our ancestors in the last century, and which accounted for all their ailments, the word magnetism accounts for nearly everything in Mr. Dewar's universe. It is in the fifth chapter that the stupendous importance of this form of energy is first sprung upon the reader:—

> "The inference from this basis [that every atom is a magnet] is astounding, for not only does it involve the magnetism of the earth as well as the magnetism of all the constituents of the earth, but it establishes beyond a doubt the *magnetism of all the products of the earth—mineral, vegetal and animal.* Every crystal, plant, animal and man is thus a magnet, whose every energy—muscular, nervous, vital, or mental—resolves itself into the familiar operations of magnetism."
>
> "Still further, as all the planets and heavenly bodies are alike in nature, so far as we can judge from analogy, so must they be governed by similar energy to the earth. Hence we reach the final conclusion, that *the bottom energy of the universe is also magnetism*" (pp. 72–73).

Having once become impregnated with this universal magnetic cult, the reader, who may otherwise have been unprepared for the series of mental shocks which is in store for him, will learn with comparative calmness that the difference of gravity at the equator and the poles is because the earth is a magnet (p. 69); he will feel sure that sooner or later "animal magnetism" mesmerism, &c., are bound to appear on the scene, and in this he will not be disappointed (p. 87); and he may even learn with equanimity that he possesses "a virtual magnetic battery" in his "vacuole or stomach" (p. 85). In the chapter on the causes of vegetal evolution we read:—

> "These huge internal fires [of the earth] are virtually *the earth's magnetic battery*, through which it is kept in life as a living planet tenanted with vegetal and animal life; hence, when all conditions are suitable, and the soil is properly saturated with water, thereby inducing suitable chemical action, the internal magnetic forces throw up a clotted vegetation on every available spot of ground on the globe. *This vegetation is but a bristling beard of earthly material ejected by the earth's magnetism;* filaments of matter, having the same relation to the earth as a man's beard to his chin, or as the bristling iron filings on a horse-shoe magnet" (p. 162).

It must be admitted that the force of magnetism can no further go, and the attributing to this agency of the vegetable-like accumulation of snow-drift on a projecting obstacle (p. 124), or the turning of a sun-flower towards the sun (p. 137), may be accepted as a mere bagatelle. Truly, as the author says, after having evolved "vegetal molecules" by a "chance flux of suitable atoms," the "magnetic laws are equal to all emergencies" (p. 159). The subtle distinction between a horse-shoe magnet as a *dry magnet*, and a plant as a *wet magnet* (p. 161) is too fine for any but ultra-metaphysical minds to grasp, but since it leads to the practical conclusion that a flower-pot full of moist earth is an artificial plant battery, it may be allowed to pass by virtue of its horticultural merits.

We confess that, in turning over the pages of this astonishing production with the object of endeavouring to learn the author's views, we have been so fascinated by his glib manipulation of the affairs of the universe, that we have allowed ourselves but little time for a critical examination of his scientific data. In fact, the work may be said to consist mainly of generalities, so that there are but few detailed statements to grasp. Here are a few specimens:—

The law of combination in definite proportions is illustrated (p. 58) by the statement that "if 20 parts of oxygen be mixed with 6 of hydrogen, only 16 parts of oxygen and 2 of hydrogen unite, 8 parts remain uncombined." This error is driven home in the following page:—

> "Innumerable elements, for instance, may often meet in suitable conditions for combination, but if unsuitable in *proportion*, no selection ensues; consequently there is no production," &c.

Hydrogen is said to be a constituent of saltpetre (p. 79).

"If a lot of chips be thrown into the water they all attract each other and form a mass" (p. 87). This is explained by the statement that sticks and stones require "stick and stone magnets to magnetise them."

"Contrasted with chemical combination, chemical decomposition has been almost ignored by chemists" (p. 101).

"Magnetic induction" is used to explain the crystallisation of a solid from a solution (p. 118).

After describing the movements of a "geometer" caterpillar, the author says: "Other caterpillars and centipedes develop feet on each ring" (p. 198).

"The fire-flies of America, which, Diogenes-like, carry a lamp with them," are classed with the bombardier beetle, both the light of the former and the discharge of the latter being described as "undoubtedly the result of electric action" (p. 201).

It need hardly be said that the propounder of a new philosophy—such as Mr. Dewar claims to be—must clear away the rubbish of previous thinkers before he can lay the foundations of his own system. Many of the current doctrines are accordingly denounced in no measured terms, and the author's emendations launched at the reader. For example, the classification of matter into simple and compound substances by chemists is scoffed at (p. 55), and here is Mr. Dewar's amendment:—

> "From unlimited corroborative evidence we believe this [duality or sexuality in elementary substances] to be the case; hence we enunciate as one of the fundamentals of the new Materialism that the normal chemical

division of the elements into metallics and non-metallics is the bottom classification of matter, the only one with confidence to be designated great."

Again (p. 56):

"With this alteration (hydrogen considered as metallic) are we warranted in ascribing to this dual classification of substance that importance, both scientifically and philosophically, which we assign it? The evidence is overwhelmingly affirmative, for no known natural product exists which does not contain both classes of these elements in combination. *Matter itself must thus be sexual.*"

There is a very widely spread mineral substance composed of silicon and oxygen which forms no inconsiderable a proportion of the earth's rocky constituents, and of which the author has no doubt heard. Silica in its various forms is certainly a natural product; and so Mr. Dewar will no doubt insist upon classifying silicon with the metals. There is also a gas composed of carbon and oxygen which is present in the atmosphere, and which is of vital importance for plant life. We should like to know how Mr. Dewar brings carbon dioxide under his "fundamental principle, which embodies one of the most salient truths in the science of the century" (p. 57).

The reader who is anxious to know how the "New Materialism" deals with the problem of life will find it disposed of in a light and airy way that might even be provocative of mirth were it not evident on every page that the author intends us to take him seriously. There is absolutely no mystery about it at all—there is no unknown force, there is no impulse different from the ordinary laws of matter. The animal is "a mere mass of conjoined magnets," containing "a virtual magnetic battery in its stomach" (p. 222). Elsewhere we are told that the plant differs from the animal in having its magnetic battery outside instead of within, and the author seems quite proud of having discovered a distinction between animals and plants that has hitherto eluded the men of science (p. 164). As for the appearance of life on the earth, it is a mere trifle to the "New Materialism":

"Under suitable conditions of heat, light and moisture, a chance flux of suitable atoms combines sexually into vegetal molecules" (p. 159) [magnetism as before].

"Even, as on a frosty night, the surface of the ground is whitened with crystals of rime, so in many a river and ocean bed the water must often coagulate with millions of vegetal and animal cells" (p. 209).

"But as igneous activity subsided to solid quiescence, and water, soil, light and heat interacted, the protoplasmic elements—oxygen, hydrogen, carbon, nitrogen, &c.—would meet in suitable proportion, and [magnetism as before] the spontaneous production of simple organisms—protophyta, protozoa and the lowest kinds of fungi and algæ—would ensue as a matter of course, &c." (p. 246).

The origin of man is described (p. 247) in a manner that can only make the reader exclaim that the New Materialism, like a certain historical character, is *capable de tout*:—

"Man's first progenitors thus probably appeared on the earth as spontaneously produced protoplasmic cells or ovules, hundreds or thousands in number, developed by sexual and magnetic affinities from a flux of the chemical elements in some ambrosial inlet of water."

No further extracts need be given, and no further criticism is necessary to justify the opinions expressed at the beginning of this notice.

R. MELDOLA.

## OUR BOOK SHELF.

*Untersuchungen über Philons und Platons Lehre von der Weltschöpfung.* Von Jakob Horovitz. Pp. xiii + 124. (Marburg: N. G. Elwart, 1900.)

DR. HOROVITZ' essay is the outcome of his thesis approved for the degree of philosophy in the University of Marburg. Its purpose is to focus the rays of light which close exegesis of the *Timaeus* throws upon the cosmogonic scheme wherein Philo effected the synthesis of Plato and Moses. While recognising the Stoic and Neopythagorean elements in Philo's teaching, Dr. Horovitz has little difficulty in showing that in both style and matter the dominant influence was Plato's. It is to the analysis, then, of Plato's creation-myth that we must turn if we would understand Philo with his enormous influence on the development of the doctrine of the Logos in Christian literature.

The ζῷον νοητόν of the *Timaeus* is no mythical duplicate of the demiurge, but distinguished as *das ewige Urbild* from the latter, whose real causal activity leads to an identification with the creative reason and ideal good of earlier dialogues. The subordinate artificers of physical creation are not the ideas as distinct from the idea of good, but in part a concession to popular theology, in part perhaps due to the place of evil in Plato's system, and the fact that dualism, though overruled, is not extinguished. In his valuable and textually supported discussion of the problems, Dr. Horovitz perhaps tends to overestimate the consistency and continuity of Plato's writings, and to underestimate the *mythus* element in the *Timaeus*.

Now Philo's intelligible world or order, the work of the one day of creation before time was or the serial "days" of the production of the world of sense began, is to be assimilated to the intelligible ζῷον of Plato as modified in conception by a use of the Stoics' metaphor of architect and supra-sensual city. It is not the Logos save in the sense in which his plan is the mind of the architect. Dr. Horovitz moves familiarly among the conceptions of Logos, intelligible world, ideal man and the like, and by adjustment of the emphasis on the various clauses of Philo's commentary produces a construction which might carry conviction. The *mutata* of Philo, and the reasons why they were *mutanda* from the Platonic theory, are well brought out. The ideal man is the work of God, the physical man is the work of God in conjunction with subordinate agents, and these powers find their natural analogue in the angels of the Jewish scheme. Platonic scholars, or those of them who have not despaired of the ζῷον as unintelligible, will find food for reflection in the one side of Dr. Horovitz' study. Theologians, students of Neoplatonism, persons who take an interest in the Hegelian *Religionsphilosophie*, may well take their starting-point from the other.

H. W. B.

*Fungus Diseases of Citrus Trees in Australia, and their Treatment.* By D. McAlpine. Pp. 132; 19 plates. (Melbourne: Brain, Government Printer, 1899.)

THIS is one of the many useful publications dealing with plant diseases issued by the Victoria Department of Agriculture. According to statistics given, the cultivation of orange and lemon trees is extending rapidly, and one successful lemon grower considers that instead of paying 62,498*l.* annually for oranges and lemons, the colony could not only produce sufficient for home consumption, but could also supply the half of Europe. Under these circumstances the appearance of a work of the kind under consideration is most opportune, more especially as it is stated to be written for the benefit of growers. It is therefore somewhat disappointing to find that a considerable portion of the text is devoted to technical descriptions of new species of fungi, a subject of no interest whatever to cultivators, more especially as many of the species enumerated are simply saprophytic forms, whose presence can do no injury. The enumeration of such species is, from a scientific standpoint, of great value; but they are altogether out of place in a work which should place before practical men the outcome of scientific research in language divested of scientific technicalities. The author considers it essential that each fungus should possess a popular name in addition to its scientific one, and there is some justification for this idea, especially when such names are of local origin, and express a definite idea, as "collar-rot," "wither-top," &c., but it is more than doubtful whether the English rendering of the scientific name, as "West Australian Septoria," or "Glœosporium-like Colletotrichum," will be adopted by the fruit grower. Fifty-one species of fungi found on citrus trees are described as new to science; this is a somewhat daring piece of work in the comparative absence of literature and herbaria. It must be borne in mind that the fact of a fungus not agreeing with any species recorded in Saccardo's "Sylloge Fungorum" by no means justifies an author in describing it as new to science.

In defining parasites and saprophytes respectively, the author states that it is not always easy to decide between the two, and the crucial test, by means of pure cultures, is not alluded to. This, however, may not be due to lack of knowledge or desire on the part of the author, who, as vegetable pathologist, is probably expected to cover too much ground; hence fundamentals, which consume time, are apt to be neglected in favour of less exact methods, which may meet with approval for the time being.

The twelve coloured plates illustrating the most pronounced and destructive forms of disease attacking lemons and oranges are excellent in every respect, and should prove of great service in enabling planters to recognise at an early stage the appearance of a disease which, if neglected, might prove disastrous. The most approved methods of treating the various diseases are given in tabular form.

*Missouri Botanical Garden. Eleventh Annual Report.* Pp. 144; 58 plates. (St. Louis, Missouri, 1900.)

THIS volume is almost entirely made up of four scientific papers representing work carried out in connection with the Missouri Botanical Garden. The papers are: a disease of *Tascodium distichum* known as "peckiness," also a similar disease of *Libocedrus decurrens* known as pin-rot, by Dr. H. von Schrenk; Agaves flowering in the Washington Botanic Garden in 1898, by Mr. J. N. Rose; A Revision of the American species of Euphorbia of the section Tithymalus occurring north of Mexico, by Mr. J. B. S. Norton; and a Revision of the species of Lophotocarpus of the United States, and a description of a new species of Sagittaria, by Mr. J. G. Smith. Dr. von Schrenk's paper has already been noticed (vol. lxi. p. 452).

Mr. Trelease, the director of the Garden, shows by these papers and his report that valuable work is being done. A small synoptical collection representative of the principal natural orders of flowering plants has been installed in the central part of the Garden, where it is proposed to continue it as a convenient means of enabling teachers in elementary schools to demonstrate to their pupils the characters of the larger plant groups. The total number of species and varieties now cultivated in the Garden is nearly ten thousand.

Mr. Trelease devoted a couple of months last summer to the study of the botany of the Alaskan coast region and the islands of Bering Sea, as a member of the Harriman Alaska Expedition. The scientific results of his work will, no doubt, be published after the large amount of material collected has been subjected to critical study.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Atmospheric Electricity and Dew-ponds.

IT is not my intention to enter into controversy with such authorities as Mr. Aitken or Mr. Wilson. I wish only to describe certain phenomena which have come under my notice, in the hope that I may help to throw some light on a subject of great importance, theoretical as well as practical.

On the chalk hills in the south-east of England there are a number of ponds known as dew-ponds. One of these was described by Gilbert White ("Natural History of Selborne," Letter 29). There is a pond of considerable size at one of the highest points of the main ridge of the South Downs close to Chanctonbury Ring. From its position it is obvious that this pond can only be fed by water precipitated into it directly from the air. Yet it always contains a considerable volume of water. At the end of the dry weather last year, when most of the ponds in the valleys were empty, this dew-pond still contained several thousand gallons. How does this pond obtain the enormous quantities of water necessary to compensate for the rapid evaporation in such an exposed position, and also to supply large flocks of sheep?

It appeared to me that there was but one possible explanation: a difference of electrical potential must cause an attraction between the particles of moisture and the summit of the hill upon which the pond is situated. It is, of course, well known that drops of rain, &c., usually have an electrical charge, but it was necessary to ascertain whether this was capable of producing such a great effect In order to test this point I took two porcelain basins of equal size and suspended them by means of silk threads from stakes driven into the ground at a high part of the ridge of the South Downs. In each of these basins was fixed an upright piece of sheet-copper. The two pieces of apparatus were placed in exactly similar positions and were in every respect identical, except that in the one case the copper screen was connected to earth by means of a wire, whereas in the other case it was insulated by the silk threads.

The apparatus was left thus during the night of April 1, 1899. There was a thick mist on the hills, so much so that I was unable to select the most favourable position for the apparatus. In the morning the amount of water in the two basins was measured. In the basin with the insulated screen there were 15·5 c.c. of water; in that with the screen connected to earth there were 18·0 c.c. This clearly confirmed my theory, for the insulated apparatus would tend to acquire an electrical charge from the particles of moisture. Consequently the attraction would be less than in the case of the apparatus which was not insulated. The insulation must have been very imperfect, for the silk became saturated with moisture as soon as the apparatus was erected. The position chosen, also, was not so favourable as it might have been. Nevertheless there was a difference of 16 per cent. in the quantities of moisture collected.

I intended to repeat and extend the experiment, but I have been unable to find an opportunity. I hope that this letter will call attention to a matter of considerable interest.

ARTHUR MARSHALL.

Chemical Department, Woolwich Arsenal, September 10.

### Huxley and his Work.

MR. HENKEL's quotation from "One Hundred and One Great Writers" (NATURE, September 6) reminds one that the taunt of being a populariser was familiar enough to Huxley himself. It recalls also the little side-thrusts with which in return the detractors were sometimes honoured. In the preface to vol. viii. of the "Collected Essays," for instance, Huxley remarks:—

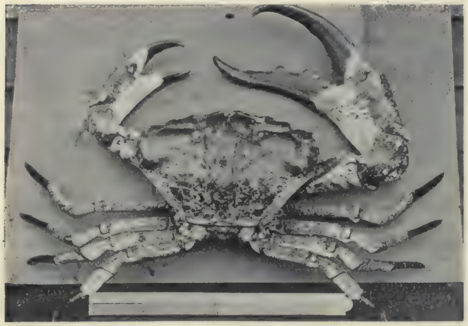
"The popularisation of science has its drawbacks. Success in this department has its perils for those who succeed. The people who fail take their revenge, as we have recently had occasion to observe, by ignoring all the rest of a man's work and glibly labelling him a mere populariser."

The belittling process, though unjustifiable, was understandable enough in those old days of controversy. To-day it seems rather uncharitable. C. Simmonds.

Thurlow Hill, West Dulwich, September 17.

### A Large Tasmanian Crab.

I am sending you a photograph of a large crab (*Psilocranium gigas*), caught in the Tasmanian waters during the present month. The crab weighed 30 lbs. It is one of the largest that has been caught in these waters. We have several specimens in the Tasmanian Museum weighing from 16 to 22 lbs. They are generally caught by the fishermen in very deep water, from fifteen to thirty fathoms, while fishing for the fish known as the Tasmanian Trumpeter (*Latris hecateia*).



I shall be glad to know whether readers of Nature have ever known of a larger *Psilocranium gigas* having been caught.

Alex. Morton.

Tasmanian Museum and Art Gallery, July 30.

### Large Puff Balls.

Having seen in some papers lately notices of large puff balls, it may probably be of interest to record the measurements of one far exceeding in size any I ever heard of.

It was found by my daughter, Mrs. Pole-Carew, in a small park belonging to me near this place, where she is residing. I took careful measurements of it at the time it was found, of which I send you a copy.

It differed in no respect except size, either inside or out, from the ordinary smooth puff ball.

*Measurements of a large Puff Ball found in Chipley Park, near Wellington, Somerset, June 12, 1900.*

W. A. Sanford.

Nynehead Court, Wellington, Somerset, September 11.

### "A Tour through Great Britain in 1727."

Is not the "Tour" queried by your reviewer (p. 417, column 2) that of Defoe, which has frequently been reprinted? and yet the first edition (1724–27) is still the best, in spite of re-editors and its extension from three vols. to four.

Ulverston. S. L. Petty.

## *PROF. HENRY SIDGWICK.*

The death of Henry Sidgwick entails the removal of one of the most potent influences that have been felt in Cambridge for the last forty years. Only a brief allusion can be made here to the time and energy which he devoted to University affairs, and to the constant and generous aid given by him to departments handicapped by poverty. As one of the strongest leaders in University policy, his power depended on a practical insight and decision of view for which those who know him only through his writings would be unlikely to credit him.

He was born in 1838. His father, the Rev. William Sidgwick, was headmaster of the Skipton Grammar School. Having been at Rugby under Dr. Goulburn, he entered Trinity College in October 1855. In 1859 he took his degree as Senior Classic and 33rd Wrangler, was elected to a Trinity Fellowship, and soon afterwards appointed Lecturer in Classics and Assistant Tutor. His interest in literary criticism and in problems of practical ethics was indicated, at this early stage, by various minor writings, of which we may specially mention an article on "The Prophet of Culture" (*Macmillan's Magazine*, 1867), in which he made a very characteristic examination of Matthew Arnold's closing lecture at Oxford. In 1868 was founded a Society, called "The Free Christian Union," of which Sidgwick was vice-president. His famous essay on "The Ethics of Conformity and Subscription" (1870) was written at the Society's request. This period of his life culminated in 1869 in the determination to give up his Trinity Fellowship on the ground that he no longer believed in the explicit creed to which the holders of Fellowships were required to subscribe under the old system of "tests." This action of Sidgwick's and the similar acts of some of his friends and contemporaries were undoubtedly important forces in the promotion of the abolition of the tests. Not long after, Sidgwick was made Lecturer and Examiner in the Moral Sciences, and later, Prælector in Moral and Political Philosophy at Trinity. In 1881 he was elected to an Honorary Fellowship there, and in 1883 he succeeded Birks in the Knightbridge Professorship of Moral Philosophy, which he resigned at the beginning of his illness last June.

As a teacher, Sidgwick exerted a profound and enduring influence, largely due to the extraordinary patience and quick perception with which he recognised and criticised the efforts of his pupils at independent thought. He presented to them an ideal of conscientious thoroughness in the pursuit of speculative truth, which has impressed and inspired even those who have developed their thought in directions far removed from his own.

Sidgwick's most important work, "The Methods of Ethics," was published in 1874 (2nd ed., 1877; 3rd, 1884; 4th, 1890; 5th, 1893). Its purpose is unlike that of most other modern works in philosophy. Not aiming directly at the construction of an ethical system, it adopts rather the Socratic method of stimulating the plain man to examine his own principles, and by self-criticism to free them from vagueness, obscurity and inconsistency. By many readers the unimpassioned, elaborately reasoned, judiciously balanced criticism is found unprofitable. But its penetrating subtlety and breadth of view are characteristics which have been recognised by all who have come under its influence, and have won for it a place amongst the philosophical classics. In general spirit it carries on the tradition of English common-sense empiricism; and, while to Sidgwick all forms of transcendentalism were repellent, yet unlike many of his predecessors in English philosophy, his criticism of opposed schools of thought was always keen and thoroughly scholarly. A different side of Sidgwick's intellectual character is shown in his work on "Practical Ethics," a collection of essays and addresses (1898), in which his speculations are applied to the very definite solution of actual problems of conduct in modern life.

In the "Outlines of the History of Ethics for English Readers," Sidgwick has supplied a most useful guide to the study of the subject. In the "Principles of Political Economy" (1st ed., 1883; 2nd, 1887) and in "The Scope and Method of Economic Science" (1885), there is a return to the older English thought, but the subject is treated with an acuteness and originality specially characteristic of Sidgwick's intellect, which have given to these works real value as contributions to economic science. The third book of the principles contains the "Art of Political Economy," which, together with "The Elements of Politics" (1st ed., 1891; 2nd, 1897), shows the keen interest always felt by Sidgwick in political and social questions, and the practical sagacity with which he handles these problems. In politics, Sidgwick combined the freedom from prejudice of the Radical with the caution of the Conservative.

Perhaps the most important practical work with which the name of Sidgwick has been associated is in connection with the higher education of women. He was the virtual founder of Newnham College, through the scheme of lectures for women which he initiated in 1869, and the house of residence which he started and persuaded Miss Clough to take charge of in 1871. In 1880, Mrs. Sidgwick having consented to become vice-principal of the second Hall of the College just opened, they both came to live there for two years; and when, after Miss Clough's death in 1892, Mrs. Sidgwick became principal of the College, they made it their permanent home.

In 1882 Sidgwick accepted the presidency of the newly formed Society for Psychical Research, in the subject-matter of which he had been interested for many years. The spirit which has characterised the proceedings of the Society, and the success which it has achieved, have been largely due to the sobriety and wisdom of Sidgwick's constant counsel and control.

---

## *PROF. JAMES EDWARD KEELER.*[1]

THE sudden death of Prof. James E. Keeler, director of the Lick Observatory, which occurred at San Francisco on August 12, removes one who stood at the very forefront of astrophysical research.

James Edward Keeler was born at La Salle, Illinois, on September 8, 1857. His qualifications for scientific work clearly showed themselves at the Johns Hopkins University, where he took an undergraduate course, and served as assistant to Prof. Hastings, with whom he observed the total solar eclipse of 1878 in Colorado.

Shortly after this he was appointed assistant at the Allegheny Observatory, where he had an important part in the long series of bolometric investigations carried on by Prof. Langley, then director of the Observatory. In July 1881 he was a member of Prof. Langley's well-known expedition to Mount Whitney, in Southern California, where an extensive region in the extreme infra-red of the solar spectrum was discovered with the bolometer. Later he studied for two years in Berlin and Heidelberg under Helmholtz and Quincke, and returned to the Allegheny Observatory, where he remained until appointed a member of the staff of the Lick Observatory. His work on Mount Hamilton commenced in 1885, and for some time he was the only astronomer at the Observatory, which was still in process of construction. In May 1891 he was elected professor of astrophysics in the Western University of Pennsylvania and director of the Allegheny Observatory.

Keeler's work at the Lick Observatory was continued in a most effective manner with the modest instrumental resources at Allegheny. With a full understanding of the art of making the most of his means, he took up photography for the first time, made himself thoroughly familiar with photographic processes, and then, with the aid of a spectrograph whose general design has been followed in the construction of the great modern spectrographs at Mt. Hamilton, Potsdam, Pulkowa and Williams Bay, he obtained the photographs of the spectra of red stars which excited so much interest at the dedication of the Yerkes Observatory. He also made an admirable series of drawings of Mars, which was published in the *Memoirs* of the Royal Astronomical Society.

In the spring of 1898 Keeler had practically decided to accept a position on the staff of the Yerkes Observatory, and would have done so had he not just then been appointed director of the Lick Observatory. His recent work on Mt. Hamilton has not been confined to the direction of the affairs of a great observatory. The remarkable success of his experiments with the Crossley reflector, of which a full account is fortunately preserved in the June number of the *Astrophysical Journal*, has impressed every one who has seen the wonderful photographs of nebulæ and star clusters made with this instrument.

Of Keeler's other contributions to science two in particular deserve present mention: his determination with the Lick telescope of the motion in the line of sight of the planetary nebulæ, and his demonstration of the meteoric constitution of Saturn's rings. The memoir which describes the first of these investigations already ranks as a classic of astrophysical literature; while the spectroscopic demonstration of the meteoric constitution of Saturn's rings is perhaps the most striking of the many effective applications which have been made of Doppler's fruitful principle.

Much more might be said of Keeler's work, but this should suffice to indicate its lasting value. It is a satisfaction to add that its merit has been widely appreciated, as has recently been evidenced by the award of the Draper and Rumford medals. He was president of the Astronomical Society of the Pacific and a councillor of the Astronomical and Astrophysical Society of America. He was elected an Associate of the Royal Astronomical Society in 1898 and a member of the National Academy of Sciences at its last meeting. His kindly and genial manner, combined with unusual tact and rare judgment, drew to him many friends, who will long mourn his loss.

---

## *NOTES.*

THE annual meeting of the Iron and Steel Institute was opened at Paris on Tuesday with an address by the president, Sir W. Roberts-Austen, K.C.B., F.R.S. It was announced that Mr. Andrew Carnegie has offered to the Institute the sum of 6500*l.* for the purpose of founding a medal and scholarship to be awarded for any piece of work that may be done in any works or University, and to be open to either sex.

IT is stated by the Paris correspondent of the *Times* that M. Yersin, to whom the Academy of Moral Sciences recently awarded a prize of 15,000 francs for philanthropic acts, has devoted the sum to his anti-plague serum establishment at Nha-trang.

THE *British Medical Journal* announces that the prize of 4000 marks voted by the Berlin Congress of Tuberculosis for the best popular work on tuberculosis as a social scourge, and the means of preventing its ravages, has been awarded to Dr. S. A. Knopf, of New York. The work will be published by the German Central Committee.

A TABLE of standard sizes of conductors for electric supply mains has been drawn up by the Cable Makers' Association and sent to electrical engineers. The table shows the nominal size of conductors, in square inches, number and diameter of strands, resistance in standard ohms per 1000 yards, and weight in lbs. per 1000 yards. It is proposed to adopt the sizes and combinations of conductors shown in the table as the basis for tenders, beginning on October 1.

---

[1] Abridged from an obituary notice contributed to *Science* of September 7 by Prof. George E. Hale.

THE list is now completed of the subjects to be discussed at the International Botanical Congress to be held in Paris from the first to the tenth of October, in connection with the Exposition, and promises a time of varied interest from both a structural and an economical point of view. Those who wish to become members, and thus to obtain the results of the Congress, should send their subscriptions (20 fr.) to M. H. Hua, Treasurer to the Congress, 2 Rue de Villersexel, Paris.

FIVE additional cases of plague, of a mild type, were reported in Glasgow on Monday. This raises the total to twenty-two plague cases, one suspected case, and 115 persons under observation. The attacked persons had been in contact with plague cases. Prof. Muir states in his report on the new cases that his experiments show without doubt that the bacillus was that of bubonic plague. He examined nine cases, both microscopically and by means of cultures, and found the same results.

AT the Geographical Congress at Berlin in October 1899 it was decided to form an International Seismological Society. The first meeting of the delegates from different countries will be held at Strassburg on April 11, 1901. The principal subjects chosen for discussion are: The organisation and extension of macroseismic investigations in all countries, the organisation of international microseismic observations, the selection of apparatus for international and local seismic observations, the annual publication of international seismic reports, and the statutes of the new society.

THE Liverpool Marine Biology Committee's station at Port Erin has been very fully occupied during the greater part of the summer, and there are at present half-a-dozen workers doing original research in the laboratory. On Saturday last a party of the Isle of Man Natural History and Antiquarian Society proceeded to Port Erin on a visit to the laboratory, and were heartily welcomed by Prof. Herdman, F.R.S. Mr. Isaac C. Thompson gave a lecture, "On the Place of the Copepoda in Nature." It was pointed out that the copepoda are of the utmost value as scavengers, as they live on the products of decomposition, putrefaction, drainage matter, &c., and by their internal laboratories convert refuse matter into most valuable food material, some copepoda constituting one of the chief sources of food for fishes, and therefore of man. Mr. Thompson said that no less than 200 species have been found in Liverpool Bay. Their beautiful organisation illustrates the truth that the wonderful structure of some animals, which can only be studied with the microscope, shows them to be as full of interest as those familiar to our ordinary vision. Besides the many free swimming copepods, there are many species found as fish parasites, living on the gills and on other external parts of our common fishes; some of these are nourished by the fish and do harm, while others do not, their presence being rather an advantage than otherwise.

THE importance of an organised and continuous system of rainfall observations is obvious to every one possessing sufficient knowledge of physical geography to know the relation of rainfall to agriculture, water supply, and all questions in which the development of natural resources is concerned. It is as essential that such observations should be systematically carried on in a thickly populated country like our own as it is that they should be made in all parts of the British Empire in which observers can be found. And when stations have been established, it is again essential that there should be a central bureau in which the observations can be collected, and their relation to one another, and to the natural features of the district determined. A report, by Mr. F. R. Johnson, upon irrigation and water supply, rainfall, and water rights in Cape Colony, published in the *Cape Agricultural Journal* (August 2), issued by the Department of Agriculture, reminds us of the value of continuous rainfall records in connection with works for irrigation and water supply. It is unusual for stream flow measurements, owing to their cost, to be available, even in the most favourable circumstances, to anything like the same extent, and it is therefore very necessary that the rainfall records should be carefully discussed, and full advantage taken of all they are capable of teaching, so that when considered and compared with shorter periods of stream flow measurement (possibly only available for an adjoining catchment) the significance of the whole may be appreciated and understood. So far this has not been done in Cape Colony, from an engineering point of view, and the need of the information is felt now that the hydrographic conditions of the Colony are being investigated. From the rainfall observations so far examined, it appears that sufficient water should be available to irrigate about five million acres of arable land; and when it is considered that this means an enhanced land value in the Colony of upwards of a hundred million pounds, the advantage of setting to work at once to digest and apply the data available to specific proposals for irrigation is apparent.

IN an article on "The Amount of the Circulation of the Carbonate of Lime and the Age of the Earth," by Prof. Eug. Dubois (*K. Akad. van Wetenschappen te Amsterdam*, 1900), it is conceded that the ocean, which derives all of its carbonate of lime from rivers or the waste of sea-cliffs, holds as much of it as it can, and that rivers are incessantly bringing a surplus. A considerable amount of carbonate of lime is often to be found in the matter carried in suspension by large rivers to the ocean, and it is obvious that in these river-waters the solution must be saturated. The quantity of carbonate of lime in river-waters is naturally determined by the rocks in the drainage areas. The author gives reasons which lead him to conclude that not more than one-thirtieth part of the carbonate of lime which rivers now discharge into the ocean is newly formed from silicates, although originally all was so derived. His calculations, based on the amount of carbonate of lime annually carried to sea by rivers, show that the formation of the whole estimated minimum amount of carbonate of lime on the earth would require about 45,000,000 of years, and that of the real amount a much larger lapse of time. He estimates that 1/2,770,000th of the total quantity of carbonate of lime of the earth participates annually in the present circulation. The final result of his investigation, though admittedly only suggestive, is that the real lapse of time since the formation of a solid crust and the appearance of life upon the globe may be more than a thousand million of years.

MR. A. GIBB MAITLAND, Government geologist of Western Australia, has issued, as *Bulletin* No. 4 of the survey reports, a general account of "The Mineral Wealth of Western Australia." This work is intended to replace the useful mining handbook which was prepared by Mr. Harry P. Woodward, and has long been out of print. The author gives a sketch of the geological features of the Colony, and then deals specially with gold, lead and copper, tin, iron, miscellaneous minerals (such as antimony, zinc, &c.), coal and graphite, guano and artesian water (with records of borings). A full list of minerals is appended, and there is a map showing the distribution of useful minerals in Western Australia, and five geological maps of particular mineral districts. The guano, which is obtained from the Abrolhos Islands and elsewhere in the north, is an important product. In 1899 upwards of two thousand tons were obtained, the total value being over 5000*l*. The amount raised last year was, however, small compared with some previous records.

A REPORT on the mineral statistics and mines of Canada for 1898 (1900), drawn up by Mr. E. D. Ingall, contains records of a great variety of mineral products. It is interesting to note that the output of coal, supplied mainly from Nova Scotia (nearly two-thirds), and from British Columbia (nearly one-third), shows an increase: the total production being nearly four million tons. Natural gas is obtained from wells in southern Ontaria. Gold shows a large increase, due to the output from the Yukon; but silver, which is almost wholly derived from British Columbia, shows a decrease. On the whole, however, the growth of Canada's mineral industries is stated to be very encouraging.

IN the memoirs of the Society "Antonio Alzate" (vol. xiv.), Señor M. Moreno publishes a discussion of the sunshine values at the Observatory of Leon (Mexico), situated in latitude 21° ·07′ N., showing the daily amounts recorded by a Campbell-Stokes instrument from June 1892 to December 1898. These values are all the more acceptable from the fact that out of some thirty observatories in the Mexican Republic, Leon appears to be the only station which furnishes a complete record of sunshine. The following figures, giving the average percentages of the possible amounts, show that the locality enjoys a large amount of bright sunshine:—winter, 71; spring, 72; summer, 59; autumn, 69; and for the year, 68. In Dr. Scott's discussion of ten years' sunshine in the British Isles, the annual average for London (City) is 24; for Greenwich, 25; and for Jersey, the sunniest part of the British Isles, 40.

THE U.S. *Monthly Weather Review* for May last contains an interesting article, by Prof. C. Abbe, on the history of modern weather prediction. He considers that the first effort towards this end was the publication of the "Mannheim Ephemerides," a series of thirteen volumes, for the years 1780–92, containing detailed meteorological observations for thirty-six stations in Europe and for three stations in America. After many years, Prof. H. W. Brandes first compiled from those observations daily weather maps for 1783 ("Beiträge zur Witterungskunde," Leipzig, 1820). In 1826 Prof. J. P. Espy organised a joint committee for the purpose of studying storms; numerous maps were constructed and many published in four successive reports (1845–60). The labours of Espy and Redfield established the fact that individual features of the weather, as well as storms, move in such a manner that their approach can be predicted by means of maps. Prof. J. Henry constructed daily weather maps from telegraphic reports, for personal study, for several years from 1848, and from 1856 onwards they were exhibited at the Smithsonian Institution. These maps were made the basis of frequent special predictions of the weather for the benefit of members of Congress and others. This date brings us down to the time of the establishment of the meteorological offices in this country and abroad.

MANY interesting points referring to the work of the Government Laboratory are mentioned by the director, Dr. T. E. Thorpe, F.R.S., in the report recently issued. A number of tinned meats were examined for the Admiralty for food preservatives, but no antiseptic other than common salt was detected. Numerous butters contained boric preservative and were artificially coloured. As usual, the use of boric acid is most prevalent in butters from France, Belgium and Australia, and is very common also in Holland. The most frequent colouring-matter is annatto, but the use of coal-tar yellows appears to be on the increase, and is especially prevalent in Holland, the United States and Australia. In the course of the year it was decided by the Board of Trade that all passenger ships should be required to carry a filter capable of delivering water free from micro-organisms. With Dr. Thorpe's assistance, a filter which satisfactorily fulfils this condition has been decided upon. As a supplement to the work of the Steel Rails Committee (see p. 437), an investigation was undertaken with the object of elucidating the mode in which the phosphorus in steel is chemically combined. The inquiry clearly showed, as has already been surmised, that the phosphorus present is, like the carbon, not infrequently in more than one form of combination. The greater part of the work done in connection with the Home Office arose out of the inquiries instituted by the Home Secretary, relative to the prevalence of lead-poisoning arising from the use of lead compounds in pottery manufacture. A considerable number of "fritts" and "glazes" have been examined, and the conditions determining the ease with which lead compounds may be extracted from them by dilute acids, comparable as regards their action with that of the gastric juice and other animal solvents, have been ascertained. As the result of the inquiry made last year, the Home Secretary has required the manufacturers of pottery to abandon the use of raw lead, and in view of the facts brought to light by the examination of the fritts and glazes, he has expressed his intention of prescribing that in future such glazes shall conform to a standard of insolubility as regards lead.

THE evidence for presence of totemism in various parts of the world is now being carefully examined, as it is beginning to be realised that a cult of animals is not necessarily the same as totemism. This is the attitude taken by Dr. C. Hose and Mr. W. MacDougall in their paper read before the recent meeting of the British Association, and to which reference will be made elsewhere in our columns. Dr. E. Westermarck, the author of the well-known work on "Human Marriage," has published some of the results of his investigations in Morocco in a paper in the *Journal* of the Anthropological Institute (vol. xxix. p. 252), entitled "The nature of the Arab *Ginn*, illustrated by the present beliefs of the people of Morocco," in which he adopts the same conclusion. The *Gnun*, as they are called in Morocco, form a special race of beings, created before Adam. They have no fixed forms, but may assume almost any shape they like. Usually they are hurtful to man. The bad *Gnun* being always ready to attack human beings, various means are used for keeping them at a distance. The *Gnun* are afraid of salt and steel, which are consequently employed as prophylactics; the best and, from a religious point of view, the correct preventive against their attacks is the recital of passages of the Koran. Dr. Westermarck adversely criticises Robertson Smith's explanation that the *Ginn* are modernised representatives of totem animals, and states that they are beings invented to explain the wonderful and mysterious in nature. They are, in fact, survivals of the early indigenous animistic beliefs of a saltless and ironless antiquity, which, at a later date, were absorbed and developed under the influence of Islâm.

THE Society for the Protection of Birds has just issued, in pamphlet form, a communication from Sir C. Lawson, which appeared in the *Madras Mail* of March 27 and April 11, pleading for the adequate protection of insectivorous birds in India. It appears that for more than a decade a law has been in force in Madras for the protection of birds, but that when, some time ago, steps were taken to extend this enactment to the other presidencies, the responsible advisers to the Indian Government did not consider that the time was ripe for such legislation. Sir C. Lawson now urges that, in great part owing to the famine, the need of bird protection by law demands immediate recognition. At present he pleads only for those insectivorous species whose wholesale slaughter for the sake of their plumage leaves grain and cotton-fields at the mercy of insect pests, thus causing "a deplorable sacrifice of human food and the materials of human raiment, besides inflicting penury on individuals and great loss to the State." The society is endeavouring to form an Indian branch, and applies for support to all interested in India. Of the excellency of the object in view we are fully assured, but it must be borne in mind that legislation of the nature proposed entails many difficulties in India, and should not be introduced without very mature consideration.

WE have received a *Bulletin* (vol. iii. No. 2) of the Madras Government Museum containing an illustrated account by the superintendent, Dr. E. Thurston, of the sea fisheries of Malabar and South Canara. A considerable portion of the pamphlet is taken up with an account of the instructions which have been recently drawn up by the author for the guidance of the officials at the various fish-curing establishments in attaining statistics of the life-history and migrations of the more abundant species of fish. As an instance of the difficulties encountered in India in obtaining statistics of this nature, it may be mentioned that "at the fish-census, 1889, the officer who was told off to make the record of fishes brought ashore, was at first driven away by the fishermen, who refused to give him the requisite information, from fear that the census was being taken with a view to increased taxation." The remainder of this valuable report is taken up by a diary made by the author during a tour of inspection of the fish-curing yards of the districts in question during the antumn of last year. Some of the most striking modes of fishing are illustrated in the plates, and details given of the amount and value of the catches at the different stations. Dr. Thurston is of opinion that a much greater variety of fish might be introduced with advantage at the dinner tables of Europeans residing in Madras than is at present the case.

AS nest-building fishes are comparatively few, naturalists will read with interest an account given in the August issue of the *American Naturalist*, by Messrs. Young and Cole, of the manner in which the brook-lamprey (*Lampetra wilderi*) makes a structure of this nature. It is believed that the males precede the females at spawning time and commence nest-building before the arrival of the latter. The nest is made among pebbles, but it does not seem that the lampreys follow any definite plan in its construction. They affix themselves to such pebbles as require removing from the nest, and then endeavour to swim straight away with them. In the case of a heavy stone two lampreys may join forces. The number of fish in a nest may vary from one to thirty or forty; but there are generally between three and twenty-five.

A PAIR of fenestræ covered with membrane have for some time been known to occur in the head of the common cockroach, and represent functional ocelli in other species of the same group. In the *American Naturalist* for August, Mr. C. Kochi records the existence of a pair of spots in the former insect, just below the aforesaid fenestræ. These spots he believes also represent the sites of another pair of ocelli which in other insects have shifted their position and coalesced to form the unpaired median ocellus.

THE *Sunday Magazine*, like many other popular journals, publishes occasional articles on scientific subjects, the one in its September issue being devoted to swimming crabs. Excellent illustrations are given of several of the species to be met with on the British coasts, while the letterpress describes their distinctive features and the leading peculiarities in their habits.

A PAPER on the life-histories of the mosquitoes of the United States, by Dr. L. O. Howard, recently published in one of its *Bulletins* by the U.S. Department of Agriculture, appears opportunely. The writer gives concise but clear descriptions, accompanied by enlarged illustrations, of all the members of the group met with in the States, devoting special attention to those of the malaria-producing genus, Anopheles. Dr. Howard calls attention to the circumstance that he advocated the employment of kerosene for the destruction of the larvæ as far back as 1894, and claims that this mode has proved more effectual, when used on a sufficiently large scale, than any other yet suggested. In certain cases, however, as in the instance of tanks containing water intended for drinking purposes, the employment of kerosene may be undesirable, and the introduction of fish, where none previously existed, is then advocated. The value of most small fishes as destroyers of mosquito larvæ is well illustrated by a natural experiment which recently took place in Connecticut. "In this case a very high tide broke away a dyke and flooded the salt meadows of Stratford, a small town a few miles away from Bridgeport. The receding tide left two small lakes, nearly side by side and of the same size. In one lake the tide left a dozen or more small fishes, while the other was fishless. An examination in the summer of 1891 showed that while the fishless lake contained tens of thousands of mosquito larvæ, that containing the fish had no larvæ."

WE have received from the publishers two numbers of the *Zeitschrift für wissenschaftliche Zoologie*—the last of vol. lxvii. and the first of lxviii. The former contains an article, by Herr E. Wasmann, describing a new genus (Termitoxenia) of wingless Dipterous insects parasitic in the nest of white ants or termites. Four species of these remarkable insects are recognised, of which one is Indian, while the other three are from Africa. Another article in the same issue, which should be of considerable interest to stock-beeders, treats of the histology of certain infusians found in the stomachs of cattle and in the cœcum of the horse. The three articles forming the first part of vol. lxviii. are all devoted to invertebrate anatomy and morphology.

THE August issue of the *Journal* of the Royal Horticultural Society contains, in addition to numerous articles dealing with fruits, vegetables and flowers, a paper treating of the scale and mealy-bug, and a second discussing the black currant-mite and its ravages. In the latter, which should be especially valuable to horticulturists, it is stated that the origin of the pest in question is unknown, but that its first recorded occurrence in the British Isles is about fifty years ago, when it was found in Scotland.

THE Natural History and Ethnographical Museum of Para, Brazil, has commenced to issue a series of memoirs; the first of these is an account by Dr. Emilio A. Goeldi, the director of the museum, of some archæological excavations which he made in 1895 of some artificial burial caves of an extinct tribe of Indians on the Rio Cunany (Goanany). Each cave consists of a circular shaft, 8 feet 2½ inches deep and 3 feet 4½ inches in diameter, the opening of which was closed by a large disc of granite. A crescentic chamber had been cut in the soil at the base of the shaft, in which were deposited a number of remarkable earthen vessels of very varied form, most of which were painted in red with peculiar designs and patterns. Some of the funeral vases were conventionally modelled to represent the human form, and others had on them various animals moulded in high relief. The memoir is illustrated by capital plates.

MESSRS. G. W. WILSON, of Aberdeen, have just issued a catalogue of more than seven hundred new lantern slides representing scenes and objects in Spain. The list should be of particular interest to teachers of geography.

WE have received the Annual Reports of the Royal Botanic Garden, Calcutta, from the superintendent, Major Prain, for the years 1898-1899, 1899-1900. Close attention has been given by the garden staff throughout the past year to the propagation and distribution of plants of economic importance.

AFTER an interval of about two years, Sir George King, late superintendent of the Royal Botanic Garden, Calcutta, continues, in the *Journal* of the Asiatic Society, Bengal, his materials for a flora of the Malayan Peninsula. The present part consists of a monograph of the Malayan species of Melastomaceæ, prepared with the assistance of Dr. O. Stapf, of the Kew Herbarium.

IN an article on the fertilisation of *Peronospora parasitica* in the *Annals of Botany* for June, Mr. Harold Wager points out that there are at present known three distinct types of fertilisation in the Peronosporeæ. In the first, represented by *Peronospora parasitica*, the oosphere and oospore are uninucleate, and fusion takes place between two nuclei only. In the second type the oosphere is uninucleate and the oospore multinucleate, and fusion is effected between two nuclei only. In the third type the oosphere and oospore are both multinucleate, and fusion takes place between a number of nuclei in pairs.

IN a paper recently read before the Linnean Society, on the origin of the Basidiomycetes, Mr. G. Massee points out the connection between the Hyphomycetes and the Protobasidiomycetes. The conidial forms of many Hyphomycetes are true Protobasidiomycetes. There is no evidence that the Autobasidiomycetes are in any way descended from the Protobasidiomycetes; while, on the other hand, there are indications that the Autobasidiomycetes may probably have been derived by gradual modifications of the spore-bearing organs or oasids of conidial forms of certain ascigerous fungi.

PROF. J. J. THOMSON's inspiring work on "The Discharge of Electricity through Gases" (Constable and Co.) has been translated into French by Dr. L. Barbillion, and published by MM. Gauthier-Villars under the title "Les Décharges électriques dans les Gaz." Dr. Barbillion adds a few notes, and Dr. C. E. Guillaume contributes a preface. The original volume was reviewed in NATURE of January 12, 1899 (vol. lix. p. 241), and the translation will doubtless be received by French physicists with the same appreciation as the work has commanded in Great Britain.

SEVERAL articles of real interest to students of science and philosophy have appeared in recent numbers of *The Open Court*. The August number contained an account of Galileo in which his work is presented in new aspects, and the opposition to his conclusions as to the movements of the earth and the character of the visible universe is in some part explained. The current number contains an instructive contribution on Greek religion and mythology, by the editor, Dr. Paul Carus, and one on animism in popular thought and in science, by Prof. E. Mach. Many of the articles in the magazine are excellently illustrated.

AN atlas for druggists and students of pharmacy, by Prof. Ludwig Koch, is in course of publication by the firm of Gebrüder Borntraeger, Leipzig, under the title of "Die mikroskopische Analyse der Drogenpulver." The first volume is to be devoted to barks and woods, and the second part of it, containing six plates, has just appeared.

THE third and fourth parts of Dr. Chun's elaborate account of the German *Valdivia* expedition have just been published by the firm of Gustav Fischer, Jena. The parts are illustrated with numerous half-tone figures and some very fine plates, and the work promises to be a very attractive narrative of an extensive voyage.

THE additions to the Zoological Society's Gardens during the past week include a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, presented by Mr. B. Stewart; a Squacco Heron (*Ardea ralloides*), South European, presented by Mr. A. F. Putz; a Black-headed Terrapin (*Damonia reevesi unicolor*) from China, an Algerian Skink (*Eumeces algeriensis*) from North-west Africa, a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. F. J. Bridgman; an European Pond Tortoise (*Emys orbicularis*), European, presented by Miss F. M. Weippert; a Wall Lizard (*Lacerta muralis*), a Tessellated Snake (*Tropidonotus tessellatus*), European, presented by Mr. Walter Hunter; two Badgers (*Meles taxus*), British; two Indian Fruit Bats (*Pteropus medius*) from India, three Black-spotted Teguexins (*Tupinambis nigropunctatus*) from South America, two Antillean Boas (*Boa diviniloqua*) from the West Indies, five Undulated Lizards (*Sceloporus undulatus*) from South-east United States, deposited.

SWIFT'S COMET (1892 I.).—In the *Annals of Harvard College Observatory* (vol. xxxii. Part ii. pp. 267–295), Prof. W. Pickering describes the photographs obtained of this comet at Arequipa during March and April 1892, illustrating his remarks by reproductions from nine of the negatives.

The plates were taken with four instruments—the 13-inch Boyden telescope, 8-inch and 2·5-inch doublets, and a 20-inch reflector; two photographs were also obtained with the 8-inch refractor provided with an objective prism of 13° refracting angle. The exposures varied from 5 to 133 minutes.

While the comet was easily visible to the naked eye, it was carefully examined with a double image prism, but no traces of polarisation could be detected in either the head or tail. The nucleus was yellowish-green in colour, giving out a triangular jet towards the sun.

The head was distinctly divisible into three parts—nucleus, bright primary envelope and an outer fainter one. The tail was composed of two sets of rays having distinctly different origins. The brighter of these sets, forming what may be called the "inner" tail, took its origin from the rear side of the inner envelope, and in some of the photographs this attains the great length of over 20° of arc. The rays were absolutely straight so far as could be determined from the photographs, and were inclined to each other about 10°. The outer tail sprung from the external faint envelope, and, in contrast to the other, was marked by conspicuous deep and wide rifts between the rays composing it.

Prof. Pickering thinks that certain periodic differences in appearance are caused by a rotation of the comet about an axis passing longitudinally through the tail. Comparisons of the Arequipa photographs with others obtained by Dr. Wolf and Prof. Barnard show that it is quite possible to detect changes from one hour to another, and from a detailed examination of the angular deviation of the rays it is probable that the rotation period is about 94-97 hours.

The photograph taken April 14 shows a strong deflection of the inner tail, but the absence of other photographs near that date render it impossible to trace the cause, and the phenomenon was not subsequently repeated.

In general, it was impossible to identify any particular feature on two successive days, but on April 6, 7, 8, a bright condensation was noticed each day, and its distance from the nucleus of the comet was found to increase day by day. These displacements were carefully measured, converted into kilometres by reference to the comet's elements, and an estimate made of the amount of the repulsive force exerted upon the comet's tail by the sun. This indicated the total repulsive force to be about 39·5 times the gravitational force. The spectrum photographs have been difficult to reduce, but the brightest region of the spectrum appears as an intense and very narrow line about $\lambda$ 3890. No indications of the hydrogen lines were seen.

## *THE BRADFORD MEETING OF THE BRITISH ASSOCIATION.*

### SECTION D.

### ZOOLOGY.

OPENING ADDRESS BY RAMSAY H. TRAQUAIR, M.D., LL.D., F.R.S.

IN opening to-day the sittings of the Zoological Section, I must first express my sense of the honour which has been conferred on me, in having been chosen as your President on this occasion, and I may add that I feel it not only as an honour to myself personally but also as a compliment to the field of investigation in which the greater part of my own original work has been done. It is a welcome recognition of the doctrine, which I, and much more important men indeed than I, have always maintained, namely, that Palæontology, however valuable, nay, indispensable, its bearings on Geology may be, is in its own essence a part of Biology, and that its facts and its teachings must not be overlooked by those who would pursue the study of Organic Morphology on a truly comprehensive and scientific basis. As I have asked on a previous occasion, "Does an animal cease to be an animal because it is preserved in stone instead of spirits? Is a skeleton any the less a skeleton because it has been excavated from the rock, instead of prepared in a macerating trough?" And I may now add—Do animals, because they have been extinct for it may be millions of years, thereby give up their place in the great chain of organic being, or do they cease to be of any importance to the evolutionist because their soft tissues, now no longer existing, cannot be imbedded in paraffin and cut with a Cambridge microtome?

These are theses which I think no one denies theoretically; but what of the practical application of the rule? For though cordially thanking my biological brethren for the honour they have done me in placing me in this chair to-day, I must ask them not to be offended if I say that in times past I have a few things against some of them at least. I refer first to the apathy concerning palæontological work, more especially where fishes are concerned, which one frequently meets with in the writings of biologists, as seen in the setting up of classifications and theories and the erection of genealogical trees without any, or with at least inadequate, inquiry as to whether such theories or trees are corroborated by the record of the rocks. But more vexatious still are the offhand proceedings of some biologists who, when they wish to complete their generalisations on the structure of a living organism, or group of organisms, by allusion to those which in geological time have gone before, do not take the trouble to consult the original palæontological memoirs or papers, or to make themselves in any way practically acquainted with the subject, but derive their knowledge at second or third hand from some text-book or similar work, which may not in every case be exactly up to date on the matters in question. Nay, more than this, I think I have seen the authors of such text-books or treatises credited with facts and illustrations which were due to the labours of hard-working palæontologists years before.

But a better time, I am convinced, is not far off, when the unity of all biological science will be recognised, not merely theoretically, but also practically by workers in every one of its branches.

Of one thing I must, however, warn those who have hitherto devoted their time exclusively to the investigation of things recent, namely, that a special training is necessary for the correct interpretation of fossil remains, especially those of the lower Vertebrata and many groups of Invertebrata. So it comes that what looks to the uninitiated eye a mere confused mass of broken bones or plates may to the trained observer afford a flood of valuable light on questions of structure previously undetermined. We must take into account the condition of the fossil as regards mineralisation and crushing; we must learn to recognise how the various bones may be dislocated, scattered, or shoved over each other, and to distinguish true sutures from mere fractures. We must carefully correlate the positive results obtained from one specimen with those afforded by others, and in this way it happens that to make a successful restoration of the exo- or endo-skeleton of a fossil fish or reptile may require years of patient research. But the thought sometimes does come up in my mind, that some people imagine that fossils, such as fishes, occur in the rocks all restored and ready, so that the author of such a restoration has no more scientific credit in his work than if he were an ordinary draughtsman drawing a perch or a trout for an illustrated book! But the student of fossil remains must not only learn to see what does exist in the specimen he examines, but also to refrain from seeing things which are not there—to know what he does not see as well as what he does see. For many grave errors have arisen from want of this necessary training, as, for instance, where the under surface of a fish's head has been described as the upper, or where markings of a purely petrological character have been supposed to indicate actual structures of the greatest morphological importance. Or we may find the most wonderful details described, which *may* indeed have existed, but for which the actual evidence is only the fertile imagination of the writer.

From this it will be apparent that though Palæontology is Biology and Biology includes Palæontology, yet as regards original research a division of labour is in most cases necessary. For though palæontological investigations are absolutely impossible without an adequate knowledge of recent zoology, yet the nature of the remains with which the palæontologist has to deal renders their interpretation a task of so different a character from that allotted to the investigation of the structure and development of recent forms that he will scarcely have time for the successful carrying out of a second line of research. Conversely, the same holds regarding the sphere of work of the recent biologist.

Now those last remarks of mine may perhaps tend to confirm an idea which I have at least been told is prevalent in the minds of recent biologists, namely, that the results of Palæontology are so uncertain, so doubtful, and so imperfect, that they are scarcely worthy of serious attention being paid to them. And the best answer I can make to such an opinion, if it really does exist, is to try to place before you some evidence that Palæontology is not mere fossil shell hunting, or the making up of long lists of names to help the geologists to settle their stratigraphical horizons, but may present us with abundance of matter of genuine biological interest.

Since the days of Darwin, there is one subject which more than all others engrosses the attention of scientific biologists. I mean the question of Evolution, or the Doctrine of Descent. Time was when controversies raged round the very idea of Evolution, and when men of science were divided among themselves as to whether the doctrine to which Darwin's theory of Natural Selection gave so mighty an impetus was or was not to be accepted. Times have, however, changed, and I hardly think that we should now find a single true scientific worker who continues to hold on by the old special creation idea. Philosophic zoologists now busy themselves either with amassing morphological evidences of Descent or with the discussion of various theories as to the factors by which organic evolution has been brought about—whether Natural Selection has been the all-sufficient cause or not, whether acquired peculiarities are transmissible, and so on.

From the nature of things it is clear that the voice of the palæontologist can only be heard on the morphological aspect of the question, but to many of us, including myself, the morphological argument is so convincing that we believe that even if the Darwinian theory were proved to-morrow to be utterly baseless, the Doctrine of Descent would not be in the slightest degree affected, but would continue to have as firm a hold on our minds as before.

Now as Palæontology takes us back, far back, into the life of the past, it might be reasonably expected that it would throw great light on the descent of animals, but the amount of its evidence is necessarily much diminished by two unfortunate circumstances. First, the terrible imperfection of the geological record, a fact so obvious to any one having any acquaintance with Geology that it need not be discussed here; and secondly, the circumstance that save in very exceptional cases only the hard parts of animals are preserved, and those too often in an extremely fragmentary and disjointed condition. But though we cannot expect that the palæontological record will ever be anything more than fragmentary, yet the constant occurrence of new and important discoveries leads us to entertain the hope that, in course of time, more and more of its pages will become disclosed to us.

Incomplete, however, as our knowledge of Evolution as derived from Palæontology must be, that is no reason why we should not appraise it at its proper value, and now and again stop for a moment to take stock of the material which has accumulated.

You are all already acquainted with the telling evidence in favour of Evolution furnished by the well-known Mammalian limbs, as well as of teeth, in which the progress, in the course of time, from the more general to the more special is so obvious that I cannot conceive of any unprejudiced person shutting his eyes to the inference that Descent with modification is the reason of these things being so. Suppose, then, that on this occasion we take up the palæontological evidence of Descent in the case of fishes. This I do the more readily because what original work I have been able to do has lain principally in the direction of fossil ichthyology; and again, because it does seem to me that it is in this department that one has most reason to complain of want of interest on the part of recent biologists, even, I may say, of some professed palæontologists themselves.

But the subject is really of so great an extent that to exhaust it in the course of an address like the present would be simply impossible, so I shall in the main limit myself to the consideration of Palæozoic forms, and this more especially seeing that we may hope for a large addition to our light on the fishes of the more recent geological formations from the fourth volume of the "Catalogue of Fossil Fishes" in the British Museum, which will soon appear from the pen of my friend, Dr. A. Smith Woodward. I need scarcely say how much his previous volume has conduced to a better knowledge of the Mesozoic forms.

Here I may begin by boldly affirming that I include the Marsipobranchii as fishes, in spite of the dictum of Cope that no animal can be a fish which does not possess a lower jaw and a shoulder-girdle. Why not? The position seems to me to be a merely arbitrary one; and it is, to say the least, not impossible that the modern Lampreys and Haggs may be, as many believe, the degenerate descendants of originally gnathostomatous forms.

To the origin of the Vertebrata, Palæontology gives us no clue, as the forerunners of the fishes must have been creatures which, like the lowest Chordata of the present day (Urochorda, Hemichorda, Cephalochorda), had no hard parts capable of preservation. And though I shall presently refer again to the subject, I may here affirm that, so far as I can read the record at least, it is impossible to derive from Palæontology any support to the view, recently revived, that the ancient fishes are in any way related to Crustacean or merostomatous ancestors.

What have we then to say concerning the most ancient fishes with which we are acquainted?

The idea that the minute bodies, known as Conodonts, which occur from the Cambrian to the Carboniferous, are the teeth of fishes and possibly even of ancient Marsipobranchs may now be said to be given up. They are now accepted by the most trustworthy authorities as appertaining to Invertebrata such as Annelides and Gephyrea.

More recently, however, Rohon[1] has described from the Lower Silurian of the neighbourhood of St. Petersburg small teeth (*Palaeodus* and *Archodus*) associated with Conodonts, and which seem to be real fish teeth, but not of Selachians, as is shown by the presence of a pulp cavity surrounded by non-vascular dentine. It is impossible to say anything more of their affinities.

Obscure and fragmentary fish remains have been obtained by Walcot, and described by Jaekel, from rocks in Colorado supposed to be of Lower Silurian or Ordovician age.[2] But doubts have been thrown on their age, and the fossils themselves, which have, it must be owned, a very Devonian look about them, are so extremely fragmentary that they do not help us much in our present purpose.

It is not till we come to the Upper Silurian rocks that we begin to feel the ground securely under our feet, though we may be certain, from the degree of specialisation of the forms which we there find, that fishes lived in the waters of the globe for long ages previously.

Characteristic of the "Ludlow bone-bed" are certain minute scales on which Pander founded the family Cœlolepidæ, having a flat or sculptured crown, below which is a constricted "neck," and then a base usually perforated by an aperture leading into a central pulp cavity. As these little bodies, looked upon by Agassiz as teeth, were shown by McCoy to be scales, and as they occurred at Ludlow in England and Oesel in Russia along with small Selachian spines (*Onchus*), they were usually considered as appertaining, with the latter, to small Cestraciont sharks. The genera *Thelodus*, *Coelolepis* and others were founded on these dermal bodies, but it is doubtful if any but the first of these names will stand.

But the aspect of affairs was altogether changed by the discovery three years ago, by the officers of the Geological Survey, of entire specimens of *Thelodus* in the Upper Silurian rocks of the South of Scotland, from which it was evident that the fish, though somewhat shark-like, could hardly be reckoned as a true Selachian.[1] *Thelodus Scoticus*, Traq., has a broad flattened anterior part corresponding to the head and forepart of the body, very bluntly rounded in front, and passing behind into right and left angular flap-like projections, which are sharply marked off from the narrow tail, which is furnished with a deeply cleft heterocercal caudal fin. Unless the flap-like lateral projections are representatives of pectorals, no other fins are present, neither do we find any teeth or jaws, nor any trace of internal skeleton; and it is only a few days since Mr. Tait, collector to the Geological Survey of Scotland, pointed out to me in a recently acquired specimen a right and left dark spot at the outer margins of the head near the front, which spots may indicate the position of the eyes.[2] A previously unknown genus, *Lanarkia*, Traq., also occurred, in which the creature had the very same form, but instead of having the skin clothed with small shagreen-like scales, possessed, in their place, minute sharp conical hollow spines, without base and open below. What we are to think of those two ancient forms, apparently so primitive, and yet undoubtedly also to a great extent specialised, we shall presently discuss.

Let us now for a moment look at the genus *Drepanaspis*, Schlüter, from the Lower Devonian of Gmünden in Western Germany.[3] We have here a strange creature whose shape entirely reminds us of that of *Thelodus*, having the same flat broad anterior part, bluntly rounded in front, and angulated behind, to which is appended a narrow tail ending in a heterocercal caudal fin, which is, however, scarcely bilobate. But here the dermal covering, instead of consisting of separate scales or spinelets, shows a close carapace of hard bony plates, of which two are especially large and prominent—the median dorsal and the median ventral—other large ones being placed around the margins, while the intervening space is occupied by a mosaic of small polygonal pieces. The position of the mouth, a transverse slit, is seen just at the anterior margin; it is bounded behind by a median mental or chin-plate, but no jaws properly so called are visible, nor are there any teeth. Then on each margin near the front of the head is a small round pit, exactly in the position of the dark spot seen in some examples of *Thelodus*, which, if not an orbit, must indicate the position of some organ of sense. Again, the tail is covered with scales after the manner of a "ganoid" fish, being rhombic on the sides, but assuming the form of long deeply imbricating fulcra on the dorsal and ventral margins. The position of the branchial opening, or openings, has not yet been definitely ascertained.

All these plates are closely covered with stellate tubercles, and we cannot escape from the conclusion that they are formed by the fusion of small shagreen bodies like those of *Thelodus*, and united to bony matter developed in a deeper layer of the skin.

If the angular lateral flaps of *Thelodus* represent pectoral fins, then we would have the exceedingly strange phenomena of such structures becoming functionally useless by enclosure in hard unyielding plates, though still influencing the general outline of the fish. Be that as it may, can we doubt that in *Drepanaspis* we have a form derived by specialisation from a Cœlolepid ancestor?

This *Drepanaspis* throws likewise a much desired light on the fragmentary Devonian remains known since Agassiz's time as *Psammosteus*. These consist of large plates and fragments of plates, composed of vaso-dentine, and sculptured externally by minute closely-set stellate tubercles, exactly resembling the scales of some species of *Thelodus*. These tubercles are also frequently arranged in small polygonal areas, reminding us exactly of the small polygonal plates of *Drepanaspis*, and, like them, often having a specially large tubercle in the centre.

[2] I am indebted to Sir A. Geikie, F.R.S., Director-General of the Geological Survey, for permission to make use of this and other facts disclosed by Mr. Tait's work in the Lesmahagow Silurians during the present summer.

[3] R. H. Traquair, *Geol. Mag.*, April 1900.

That *Psammosteus* had an ancestry similar to that of *Drepanaspis* can also hardly be doubted.

Finally, in the well-known *Pteraspis* of the Upper Silurian and Lower Devonian formations we have a creature which also has the head and anterior part of the body enveloped in a carapace, to which a tail covered with rhombic scales is appended behind, and, though the caudal fin has never been properly seen, such remains of it as have occurred distinctly indicate that it was heterocercal in its contour. The plates of the carapace have a striking resemblance in general arrangement to those of *Drepanaspis*, though the small polygonal pieces have disappeared, and there is a prominent pointed rostrum in front of the mouth; and it is to be noted that the small round apertures usually supposed to be orbits are in a position quite analogous to that of the sensory pits in *Drepanaspis*. The plates of the carapace of *Pteraspis* are not, however, tuberculated, but ornamented by fine close parallel ridges, the microscopic structure of which, along with their frequent lateral crenulation, leaves no doubt in our minds that they have been formed by the running together in lines of *Thelodus*-like shagreen grains. An aperture supposed to be branchial is seen on the plate forming the posterior angle of the carapace on each side.

Until these recent discoveries concerning the Cœlolepidæ and Drepanaspidæ, *Pteraspis* and its allies, *Cyathaspis* and *Palaeaspis*, constituted the only family included in the order Heterostraci of the sub-class Ostracodermi, distinguished, as shown by Lankester, by the absence of bone lacunæ in the microscopic structure of their plates. It is now, however, clear that we can trace them back to an ancestral family in which the external dermal armature was still in the generalised form of separate shagreen grains or spinelets.

But the Ostracodermi are usually made to include two other groups or orders, namely the Osteostraci and the Asterolepida.[1]

The Osteostraci are distinguished from the Heterostraci by the possession of lacunæ in their bone structure, and by having the eyes in the middle of the head-shield instead of at the sides. *Cephalaspis*, which occurs from the Upper Silurian to the top of the Devonian, is the best known representative of this division. Instead of a carapace, we find a large head-shield of one piece, though its structure shows evidence of its having been originally composed of a mosaic of small polygonal plates, and it is also to be noted that the surface is ornamented by small tubercles, there frequently being one larger in size in the centre of each polygonal area. The posterior-external angles of the shield project backward in a right and left pointed process or *cornu*, scarcely developed in *C. Murchisoni*, internal to which, and also organically connected with the head-shield, is a rounded flap-like structure, which strongly reminds us of the lateral flaps of the Cœlolepidæ. The body is covered with scales, which on the sides are high and narrow; there is a small dorsal fin, and the caudal, though heterocercal, is not bilobate. It is scarcely necessary for me to add that we find just a little evidence of jaws or of teeth as in the case of the Heterostraci.

The association of the Heterostraci and Osteostraci in one sub-class of Ostracodermi has been strongly protested against by Prof. Lankester and Dr. O. M. Reis, but here the Scottish Silurian strata come to the rescue with a form which I described last year under the name of *Ateleaspis tessellata*, and of which some more perfect examples than those at my disposal at that time have recently come to light through the labours of Mr. Tait, of the Geological Survey of Scotland.

Here we have a creature whose general form reminds us strongly of *Thelodus*, but whose close affinity to *Cephalaspis* is absolutely plain, were it only on account of the indications of orbits on the top of the head.

The expanded anterior part which here represents the head-shield of *Cephalaspis* shows not the slightest trace of cornua, but forms posteriorly a gently rounded lobe on each side, clearly suggesting that the cornual flaps of *Cephalaspis* are homologous with and derivable from the lateral expanses in the Cœlolepidæ. This cephalic covering is composed of numerous small polygonal plates like those of which the head-shield in *Cephalaspis* no doubt originally consisted, and the minute tubercles which cover their outer surfaces also suggest that the superficial layer was formed by the fusion of Cœlolepid scales. The body is covered with rhombic scales, sculptured externally with tubercles and wavy transverse ridges, and arranged in lines having the same general direction as the scutes of *Cephalaspis*, from which we may infer that the latter originated from the fusion of scales of similar form. The fins are as in *Cephalaspis*, there being one small dorsal situated far back, and a heterocercal caudal, which is triangular in shape, and not deeply cleft into upper and lower lobes as in the Cœlolepidæ. Finally, the scales, on microscopic examination, show well-developed bone lacunæ in their internal structure.

That *Ateleaspis* belongs to the Osteostraci there is thus not the smallest doubt, but its general resemblance to the Cœlolepidæ in its contour anteriorly led me to regard it as an annectent form, and consequently to believe that there is after all a genuine genetic connection between the Heterostraci and the Osteostraci. And I have not seen reason to depart from that opinion even though *Ateleaspis* turns out to be still closer to *Cephalaspis* than was apparent in the original specimens.

If this be so, then *Cephalaspis*, as well as *Pteraspis* and its allies, is traceable to the Cœlolepidæ, shark-like creatures in which, as we have already seen, the dermal covering consists of small shagreen-like scales, or of minute hollow spines, and consequently all theories as to the arthropod origin of the Ostracodermi, so far as they are founded on the external configuration of the carapace in the more specialised forms, must fall to the ground. And from the close resemblance of these scales of *Thelodus* to Elasmobranch shagreen bodies—for forty-five years they had been, by most authors, actually referred to the Selachii—I concluded that the Cœlolepidæ owed their origin to some form of primitive Elasmobranchs. That is, however, not in accordance with the view of the late Prof. Cope, that the Ostracodermi are more related to the Marsipobranchii, and that, from the apparent absence of lower jaw, they should be placed along with the last-named group in a class of Agnatha, altogether apart from the fishes proper. And Dr. Smith Woodward, who is inclined to favour Cope's theory, has expressed his view that the similarity of the Cœlolepid scales to Elasmobranch shagreen is no proof of an Elasmobranch derivation, but that such structures, representing the simplest form of dermal hard parts, may have originated independently in far distant groups.[1] Knowing what we do of the occurrence of strange parallelisms in evolution, it would not be safe to deny such a possibility. But as to a Marsipobranch affinity, I would point out that the apparent want of lower jaw among the hard parts which nature has preserved for us is no proof of the absence of a Meckelian cartilage among the soft parts which are lost to us for ever; and also, as Prof. Lankester has remarked, that there is no evidence whatever that any of the creatures classed together as Ostracodermi were monorhinal like the Lampreys. The only fossil vertebrate having a single median opening, presumably nasal, in the front of the head is *Palaeospondylus*, but, whatever be the true affinities of this little creature, at present the subject of so much dispute, I think we may be very sure that it is not an Ostracoderm.

The Devonian "Antiarcha" or Asterolepida, of which *Pterichthys* is the best known genus, are also usually placed in the Ostracodermi, with which they agree in the possession of a carapace of bony plates, in the absence of distinct lower jaw or teeth, in the non-preservation of internal skeleton, and in having a scaly tail furnished with a heterocercal caudal fin, and, as in the Cephalaspidæ, also with a small dorsal. But they have in addition a pair of singular jointed thoracic limbs, evidently organs of progression, which are totally unlike anything in the Osteostraci or in the Heterostraci, or indeed in any other group of fishes. These limbs are covered with bony plates and hollow inside, but though I once fancifully compared them in that respect with the limbs of insects, I must protest strongly against this expression of mine being quoted in favour of the arthropod theory of the derivation of the Vertebrata!

Nor do I think that there is any probability in the view published by Simroth nine years ago,[2] namely, that *Pterichthys* may have been a land animal which used its limbs for progression on dry ground, and that the origin of the heterocercal tail was the bending up of the extremity of the vertebral axis caused by its being dragged behind the creature in the act of walking. That view was promulgated before the discovery of the membranous expanse of the caudal fin in this genus.

But though the Asterolepida are apparently related to and includible in the Ostracodermi, the geological record is silent as to their immediate origin, no intermediate forms having been found connecting them more closely with either the Heterostraci or the Osteostraci. In the possession of bone lacunæ and of a dorsal fin they have a greater resemblance to the latter, but it may be looked upon as certain that they could have had no direct origin from that group.

---

[1] To these I myself recently added a fourth, the Anaspida, for the remarkable Upper Silurian family of Birkeniidæ, but as these throw no light as yet on the problem of Descent they may at present be only mentioned.

As regards the Ostracodermi as a sub-class, they become extinct at the end of the Devonian epoch, and cannot be credited with any share in the evolution of the fishes of more recent periods, not even if we restore the Coccosteans or Arthrodira to their fellowship. To the latter most enigmatical group, which I shall still continue to look upon as fishes, I shall make some reference further on.

Coming now to say a word regarding the Elasmobranchii, it is plain from the fin-spines found in Upper Silurian rocks that they are of very ancient origin, and that if we only knew them properly they would have a wonderful tale of evolution to tell. But their internal skeleton is from its nature not calculated for preservation, and for the most part we only know those creatures from scattered teeth, fin-spines and shagreen, specimens showing either external configuration or internal structure being rare, especially in Palæozoic strata. But from what we do know, there is no doubt that the ancient sharks were less specialised than those of the present day, and that the recent Notidanids still preserve peculiarities which were common in the Selachii of past ages.

If we ask whether the fossil sharks throw any light on the disputed origin of the paired limbs, whether from the specialisation of right and left lateral folds, or whether that type of limb called "archipterygium" by Gegenbaur, consisting of a central jointed axis with pre- and post-axial radial cartilage attached, was the original form, I fear we get no very definite answer from Elasmobranch palæontology. The paired fins of the Upper Devonian shark, *Cladoselache*, as described by Bashford Dean, Smith Woodward and others, seem to favour the lateral fold theory, and Cope pointed to the right and left series of small intermediate spines which in some Lower Devonian Acanthodei (*Parexus* and *Climatius*) extend between the pectorals and ventrals as evidence of a former continuous lateral fin. So also, if I am right in looking on the lateral flaps of the Cœlolepidæ as fins, the evidence of these ancient Ostracodermi would be in the same direction.

But, on the other hand, we have the remarkable group of Pleuracanthidæ, extending from the Lower Permian back to the Upper Devonian, in which the paired fins are represented by an "archipterygium" which in the pectoral at least is biserial.

From this biserial "archipterygium" in the Pleuracanthidæ, Prof. A. Fritsch, ten years ago,[1] derived the tribasal arrangement of modern sharks, much according to the Gegenbaurian method, effecting, however, a compromise with the lateral fold theory by assuming that the Pleuracanth form originated from one, consisting of simple parallel rods, like that described in *Cladoselache*.

In my description of the pectoral fin of the Carboniferous *Cladodus Neilsoni*[2] I have shown that the cartilaginous structures apparently present an uniserial archipterygium intermediate between the arrangement in *Pleuracanthus* and that in the modern sharks, but I felt compelled to acknowledge that the specimen might also be interpreted in exactly the opposite way, namely, as an example of a transition from the "ptychopterygium" of *Cladoselache* to the Pleuracanth and Dipnoan limb. And so in fact this fin of *Cladodus* is claimed in support of their views by both parties in the dispute.

When we add that Semon emphatically denies that there is any proof for considering that the pectoral fin of *Cladoselache* is primitive in its type,[3] and that Campbell Brown, in his recent paper on the Mesozoic genus *Hybodus*,[4] supports Gegenbaur's theory, it will be seen that Elasmobranch palæontology has not as yet uttered any very clear or decided voice on the question as to whether the so-called archipterygium is the primary form of paired fin in the fish, or only a secondary modification. We shall now inquire if we can obtain any more light on the subject from the Crossopterygii and Dipnoi.

The Crossopterygii are a group of Teleostomous fishes, characterised externally by their jugular plates and lobate paired fins, and represented in the present day only by the African genera *Polypterus* and *Calamoichthys*, which together form the peculiar family Polypteridæ. The Crossopterygii appear suddenly in the middle of the Devonian period, their previous ancestry being unknown to us.

Four families[1] are known to us in Palæozoic times—the Osteolepidæ, Rhizodontidæ, Holoptychiidæ and Cœlacanthidæ, but it is only with the first three that we have at present to deal. The Osteolepidæ and Rhizodontidæ, which appear together in Middle, and die out together in Upper Palæozoic times, resemble each other very closely. In both we have the paired fins, more especially the pectoral, obtusely or subacutely lobate; there are two separate dorsal fins, one anal, and the caudal, which is usually heterocercal, though in some genera it is more or less diphycercal. In both the teeth are conical and have the same complex structure, the dentine being towards the base thrown into vertical labyrinthic folds, exactly as in the Stegocephalian Labyrinthodonts, and this along with the lung-like development of the double air-bladder in the recent Polypteridæ has given rise to the view that from these forms the Stegocephalia have originated. The nasal openings must have been on the under surface of the snout, as in the Dipnoi.

Of these two so closely allied families we must conclude that the Osteolepidæ are the more primitive, as in them the scales are acutely rhombic and usually covered with a thick layer of ganoine, while in the Rhizodontidæ they are rounded, deeply imbricating, and normally devoid of the ganoine layer, which, however, occasionally recurs on the scales of *Rhizodopsis* and the fin-rays of *Gyroptychius*.

What then of the structure of the paired fins? Fortunately in the Rhizodont genera *Tristichopterus* and *Eusthenopteron* the internal skeleton of the lobe was ossified, and what we see clearly exhibited in the pectoral of some specimens is striking enough. We have a basal piece attached to the shoulder-girdle and followed by a median axis of four ossicles placed end to end. The first of these shows on its postaxial margin a strong projecting process, while to its preaxial side, close to its distal extremity, a small radial piece is obliquely articulated, and a similar one is joined also to the second and third segments of the axis. The arrangement in the ventral fin is essentially similar.

In fact, we have in the Rhizodontidæ a short uniserial "archipterygium," and the question is, Has this been formed by the shortening up and degeneration of an originally elongated and biserial one, or on the other hand do we find here a condition in which the stage last referred to has not yet been attained? This question is inseparable from the next, whether the Rhizodonts or the Holoptychians form the most advanced type?

The Holoptychiidæ resemble the Rhizodontidæ extremely closely in their external head-bones, in their rounded, deeply imbricating scales, and in the form and arrangement of their median fins. But the teeth show a more complex and specialised structure than those of the Rhizodontidæ; the simple vertical vascular tubes formed by the repeated folding of the dentine in that family being connected by lateral branches around which the dentine tubules are grouped in such a way as to give rise in transverse sections to a radiating arborescent appearance; hence the term "dendrodont." In this respect, then, the Holoptychiidæ show an advance on the Rhizodontidæ—what then of the paired fins? While the ventral remains subacutely lobate, as in the previous family, the pectoral has now assumed an elongated *acutely lobate* shape, with the fin-rays arranged along the two sides of a central scaly axis exactly as in the Dipnoi; and though the internal skeleton has not yet been seen, yet, judging by analogy, we cannot escape the belief that it was in the form of a complete biserial "archipterygium."

What, then, is the condition of affairs in the oldest known Dipnoan?

The oldest member of this group with whose configuration we are acquainted is *Dipterus*, which likewise appears in the middle of the Devonian period simultaneously with the Osteolepidæ, Rhizodontidæ and Holoptychiidæ. In external form it closely resembles a Holoptychian, having a heterocercal caudal fin, two similarly placed dorsals, one anal, and circular imbricating scales, which, however, have the exposed part covered with smooth ganoine. But now we have the ventrals as well as the pectorals acutely lobate in shape, and presumably archipterygial in structure; the top of the head is covered with many small plates, there is no longer a dentigerous maxilla, the skull is autostylic, and the palatopterygoids and the mandibular splenial are like those of *Ceratodus* and bear each a tooth-plate with radiating ridges.

[1] *Five*, if we include the singular and still imperfectly known Tarrasiidæ of the Lower Carboniferous.

Now, comparing *Dipterus* with the recent *Ceratodus* and *Protopterus*, the first conclusion we are likely to draw is, that the older Dipnoan is a very specialised form, that its heterocercal tail and separate dorsals and anal are due to specialisation from the continuous diphycercal dorso-ano-caudal arrangement in the recent forms, that the Holoptychiidæ were developed from it by shortening up of the ventral archipterygium, as well as by the changes in cranial structure, and that the Rhizodontidæ and Osteolepidæ are a still more specialised series in which the pectoral archipterygium has also shared the fate of the ventral in becoming shortened up and uniserial.

Five years ago, however, M. Dollo, of the Natural History Museum at Brussels, the well-known describer of the fossil reptiles of Bernissart, proposed a new view to the effect that the process of evolution had gone exactly in the opposite direction;[1] and after long consideration of the subject I find it difficult to escape from the conclusion that this view is more in accordance with the facts of the case, though, as we shall see, it also has its own difficulties.

I have already indicated above that we are, on account of the more specialised structure of the teeth, justified in considering the Holoptychians, with their acutely lobate pectorals, a newer type than the Rhizodonts, even though they did not survive so long in geological time. What, then, of the question of autostyly?

We do not know the suspensorium of *Holoptychius*, but that of the Rhizodontidæ was certainly hyostylic, as in the recent *Polypterus*. Now as there can be no doubt that the autostylic condition of skull is a specialisation on the hyostylic form, as seen also in the Chimæroids and in the Amphibia, to suppose that the hyostylic Crossopterygii were evolved from the autostylic Dipnoi is, to say the least, highly improbable; in my own opinion, as well as in that of M. Dollo, it will not stand. And if we assume a genetic connection between the two groups it is in accordance with all analogy to look on the Dipnoi as the children and not as the parents of the Crossopterygii.

M. Dollo adopts the opinion of Messrs. Balfour and Parker that the apparently primitive diphycercal form of tail of the recent Dipnoi is secondary, and caused by the abortion of the termination of the vertebral axis as in various "Teleostei," so that no argument can be based on the supposition that it represents the original "protocercal" or preheterocercal stage. Very likely that is so, but it is not of so much importance for the present inquiry, as both in the Osteolepidæ and Rhizodontidæ we find among otherwise closely allied genera some which are heterocercal, others more or less diphycercal. *Diplopterus*, for example, differs from *Thursius* only by its diphycercal tail, and in like manner among the Rhizodontidæ *Tristichopterus* is heterocercal, *Eusthenopteron* is nearly diphycercal, and there can be no doubt that, in spite of this, their caudal fins are perfectly homologous structures.

But of special interest is the question of the primitive or non-primitive nature of the continuity of the median fins in the recent Dipnoi. Like others I was inclined to believe it primitive, and that the broken-up condition of these fins in *Dipterus* was a subsequent specialisation, and in fact gave the series *Phaneropleuron*, *Scaumenacia*, *Dipterus macropterus* and *D. Valenciennesii* as illustrating this process of differentiation. This view of course draws on the imperfection of the geological record in assuming the existence of ancient pre-Dipterian Dipnoi with continuous median fins, which have never yet been discovered. But Dollo, using the very same series of forms, showed good reason for reading it in exactly the opposite direction.

The series is as follows:—

(1) *Dipterus Valenciennesii*, Sedgw. and Murch., from the Orcadian Old Red, and the oldest Dipnoan with whose shape we are acquainted, has two dorsal fins with *short* bases, a heterocercal caudal, and one short-based anal.

(2) *Dipterus macropterus*, Traq., from a somewhat higher horizon in the Orcadian series, has the base of the second dorsal much *extended*, the other fins remaining as before.

(3) In *Scaumenacia curta* (Whiteaves), from the Upper Devonian of Canada, the first dorsal has advanced considerably towards the head, and its base has now become elongated, while the second has become still larger and more extended, though still distinct from the caudal posteriorly.

(4) In *Phaneropleuron Andersoni*, Huxley, from the Upper Old Red of Fifeshire, the two dorsal fins are now fused with each other and with the caudal, forming a long continuous fin along the dorsal margin, while the tail has become nearly diphycercal, with elongation of the base of the lower division of the fin. But the anal still remains separate, narrow, and short-based.

(5) In the Carboniferous *Uronemus lobatus*, Ag., the anal is now also absorbed in the lower division of the caudal, forming now, likewise on the hæmal aspect, a continuous median fin behind the ventrals. There is also a last and feeble remnant of a tendency to an upward direction of the extremity of the vertebral axis.

(6) In the recent *Ceratodus Forsteri*, Krefft, the tail is diphycercal (secondary diphycercy), the median fins are continuous, the pectorals and ventrals retain the biserial archipterygium, but the cranial roof-bones have become few.

(7) In *Protopterus annectens*, Owen, the body is more eel-like, and the paired fins have lost the lanceolate leaf-like appearance which they show in *Ceratodus* and the older Dipnoi They are like slender filaments in shape, with a fringe on one side of minute dermal rays; internally they retain the central jointed axis of the "archipterygium," but according to Wiedersheim the radials are gone, except it may be one pair at the very base of the filament.

(8) Finally, in *Lepidosiren paradoxa*, Fitz., the paired fins are still more reduced, having become very small and short, with only the axis remaining.

From this point of view, then, *Dipterus*, instead of being the most specialised Dipnoan, is the most archaic, and the modern *Ceratodus*, *Protopterus* and *Lepidosiren* are degenerate forms, and instead of the Crossopterygii being the offspring of *Dipterus*-like forms, it is exactly the other way, the Dipnoi owing their origin to Holoptychiidæ, which again are a specialisation on the Rhizodontidæ, though they did not survive so long as these in geological time. Consequently the *Ceratodus* limb, with its long median segmented axis and biserial arrangement of radials, is not an archipterygium in the literal sense of the word, but a derivative form traceable to the short uniserial type in the Rhizodonts. But from what form of fin *that* was derived is a question to which palæontology gives us no answer, for the progenitors of the Crossopterygii are as yet unknown to us.

Plausible and attractive as this theory undoubtedly is, and though it relieves the palæontologist from many difficulties which force themselves upon his mind if he tries to abide by the belief that the Dipnoan form of limb had a selachian origin, and was in turn handed on by them to the Crossopterygii, yet it is not without its own stumbling-blocks.

First, as to the dentition, on which, however, M. Dollo does not seem to put much stress, it is impossible to derive *Dipterus* *directly* from the Holoptychiidæ, unless it suddenly acquired, as so many of us have to do as we grow older, a new set of teeth. The dendrodont dentition of *Holoptychius* could not in any way be transformed into the ctenodont or ceratodont one of *Dipterus*: both are highly specialised conditions, but in different directions. Semon has recently shown that the tooth-plates of the recent *Ceratodus* arise from the concrescence of numerous small simple conical teeth, at first separate from each other.[1] Now this stage in the embryo of the recent form represents to some extent the condition in the Uronemidæ of the Carboniferous and Lower Permian, which stand quite in the middle of Dollo's series.

Again, the idea of the origin of the Dipnoi from the Crossopterygii in the manner sketched above cuts off every thought of a genetic connection between the biserial archipterygium in them and in the Pleuracanthidæ, so that we should have to believe that this very peculiar type of limb arose independently in the Selachii as a parallel development. It may be asked, Why not? We may feel perfectly assured that the autostylic condition of the skull in the Holocephali arose independently of that in the Dipnoi, as did likewise a certain amount of resemblance in their dentition. But those who from embryological grounds oppose any notion of the origin of the Dipnoi from "Ganoids" might here say, if they chose, If so, why should not also the same form of limb have been independently evolved in Crossopterygii?

Accordingly, while philosophic palæontology is much indebted to M. Dollo for his brilliant essay, and though we must agree with him in many things, such as that the Crossopterygii were not derived *from* the Dipnoi, and that the modern representatives of the latter group are degenerate forms, yet as to the *immediate* ancestry of the Dipnoi themselves, and the diphyletic origin of the so-called archipterygium, we had best for the present keep an open mind.

[1] "Die Zahnentwickelung des *Ceratodus Forsteri*." (Jena, 1899.)

In his "Catalogue of the Fossil Fishes" in the British Museum (vol. ii. 1891), Dr. Smith Woodward, following the suggestion of Newberry in 1875, classified the Coccosteans or "Arthrodira" as an extremely specialised group of Dipnoi. At first I was much taken with that idea, but after looking more closely into the subject I began to doubt it extremely. My own opinion at present is that the Coccosteans are Teleostomi belonging to the next order, Actinopterygii; but Prof. Bashford Dean, of New York, will not have them to be even "fishes," but places them in a distinct class of "Arthrognatha," which he places next to the Ostracophori (= Ostracodermi), even hinting at a possible union with them, whereby the old "Placodermata" of McCoy would be restored. It will, therefore, be better to leave them out of consideration for the present, pending a thorough re-examination of their structure and affinities.

We come then to the great order of Actinopterygii, to which a large number of the fishes of later Palæozoic age belong, as well as the great mass of those of Mesozoic, Tertiary and Modern times. Of these we first take into consideration the oldest sub-order, namely, the Acipenseroidei or Sturgeon tribe, in which the dermal rays of the median fins are more numerous than their supporting ossicles, while the tail is, in most, completely heterocercal. And the oldest family of Acipenseroids with which we are acquainted is that of the Palæoniscidæ, which, in addition to well-developed cranial and facial bones, has the body normally covered with rhombic ganoid scales furnished with peg-and-socket articulations. Of this family one genus, *Cheirolipis*, appears in the same Devonian strata (Orcadian series) with the earliest known Crossopeterygii, and of its immediate ancestry we know no more than we do of theirs. *Cheirolepis* is a fully evolved palæoniscid, as shown by its oblique suspensorium, wide gape, and other points of its structure. In the Lower Carboniferous rocks of Scotland, where the family attains an enormous development, we find one or two genera, *e.g.* *Canobius*, which appear less specialised, as the suspensorium is nearly vertical, and the mouth consequently smaller.

This family endures up to the Purbeck division of the Jurassic formation, and in the Carboniferous *Cryphiolepis*, the Lower Permian *Trissolepis* and the Jurassic *Coccolepis* we find the same degeneration of the rhombic scales into those of a circular form and imbricating arrangement, which we find repeated in other groups of "Ganoids." In fact, in one Carboniferous genus, *Phanerosteon*, the scales disappear altogether with the exception of those on the body prolongation in the upper lobe of the caudal fin, and a few just behind the shoulder-girdle.

And in these Palæozoic times we notice also a side branch of the Palæoniscidæ, constituting the family Platysomidæ, in which, while the median fins acquire elongated bases, the body becomes shortened up and deep in contour. The scales become high and narrow, their internal rib and articular spine coincident with the anterior margin; the suspensorium, too, instead of swinging back as in the typical Palæoniscidæ, tends to be directed obliquely forward, while the snout becomes simultaneously elongated in front of the nares.

A most interesting series of forms can be set up, beginning with *Eurynotus*, which, though it has the platysomid head contour and a long-based dorsal, has only a slight deepening of the body, and still retains the palæoniscid squamation and a short-based anal fin. In *Mesolepis*, which resembles *Eurynotus* in shape, being only slightly deeper, we have now the characteristic platysomid squamation, and the base of the anal fin is considerably elongated. *Platysomus* has a still more elongated anal fin, and the body is rhombic; while in *Cheirodus* the body is still deeper in contour, with peculiar dorsal and ventral peaks, long fringing dorsal and anal fins, while the ventrals seem to have disappeared altogether. Here also, as in the allied genus *Cheirodopsis*, the separate cylindro-conical teeth characteristic of the family are, on the palatal and splenial bones, replaced by dental plates, reminding us of those of the Dipnoi. Certainly the Platysomidæ seem to me to form a morphological series telling as strongly in favour of Descent as any other in the domain of palæontology.[1]

If we now return to the Palæoniscidæ we find that they dwindled away in numbers in the Jurassic rocks, and finally became extinct at the close of that epoch. But already in the Lias (leaving the Triassic Catopteridæ out of consideration for the present) we find that they have sent off another offshoot sufficiently distinct to be reckoned as a new and separate family, namely, the Chondrosteidæ, in which the path of degeneration, in all but the matter of size, seems to have been entered on.

In the genus *Chondrosteus*, though the palæoniscid type is clearly traceable in the cranial structure, there is marked degeneration as regards the amount of ossification, and though the suspensorium is still obliquely directed backward the toothless jaws are comparatively short, and the mouth seems now to have become tucked in under the snout as in the recent sturgeon. Then the scales have entirely disappeared from the skin except on the upper lobe of the heterocercal caudal fin, where they are still found arranged exactly as in the Palæoniscidæ.

*Chondrosteus* in fact conducts us to the recent Acipenseroids—the Polyodontidæ (Paddle-fishes) and Acipenseridæ (Sturgeons).

The first of these resembles *Chondrosteus* in the nakedness of the skin, except on the upper lobe of the caudal fin,[1] the more palæoniscid aspect of the external cranial plates, such of them as remain, for they are now still further reduced. But in front of the mouth and eyes there is an addition in the form of an enormous vertically flattened paddle-shaped snout covered above and below with a large number of small ossifications.

The sturgeons have, however, nearly altogether lost the palæoniscid arrangement of the cranial roof-bones, which, strange to say, now exhibit an arrangement reminding us of that in *Dipterus*, and the external facial plates are still more reduced than even in *Polyodon*; but we may note a very strong resemblance to *Chondrosteus* in the position of the mouth, the edentulous jaws, and the jugal bone, indeed also in the palatal apparatus.

So the sturgeons and paddle-fishes of the present day would seem to be the degenerate, though bulky, descendants of the once extensively-developed group of Palæoniscidæ, even as the modern Dipnoi are degenerated from those of Palæozoic times.

We now notice another *apparent* offshoot of the Palæoniscidæ, namely, the family of Catopteridæ (*Catopterus* and *Dictyopyge*), which is limited to rocks of Triassic age. Unfortunately the osteology of the head is not well known, but Dr. Smith Woodward's observations are to the effect that both the head and shoulder-girdle are of palæoniscoid type. The relationship of these small fishes to the Palæoniscidæ is shown by the general shape, the number and position of the fins, the rhombic ganoid scales, and the close arrangement of the rays of the median fins. But the rays of the dorsal and anal fins are now almost equal in number to their supporting ossicles, and the tail has become only abbreviate heterocercal. That is to say, the caudal body prolongation no longer proceeds to the termination of the upper lobe, which is reduced in size and in the number of its rays. The Catopteridæ are obviously an annectent group, as although from their abbreviate heterocercal tail they have usually been placed in the next sub-order, Dr. Smith Woodward prefers to look upon them as Chrondrostei (*i.e.* Acipenseroidei).[2] Wherever we place them they express the beginning of a set of changes towards a more modern type of fish, which are emphasised in the great series of Lepidosteoid fishes (Protospondyli + Ætheospondyli of Smith Woodward), being the fishes more or less allied to the recent Bony Pike of North America.

But these changes must have been well advanced before the Triassic era, for already in the Upper Permian occurs the genus *Acentrophorus*, whose fellowship with *Semionotus*, *Lepidotus*, and all the rest of the series of Mesozoic semi-heterocercal "Ganoids" is at once obvious.

If we look at the configuration of a typical Jurassic member of this series, such as *Lepidotus* or *Eugnathus*, we shall at once see that we are a stage nearer the modern osseous fish. Though the scales are bony, rhombic, and ganoid we are struck by the "Teleostean"-like aspect of the external bones and plates of the head, the rays of the dorsal and anal fins are fewer and correspond in their number to that of the internal supports or "interspinous" bones, while in the caudal we see again the semi-heterocercal or abbreviate-heterocercal condition we noticed above in *Catopterus*.

---

[1] R. H. Traquair, "Structure and Affinities of the Platysomidæ," *Trans. Roy. Soc. Edin.*, xxix. 1879, pp. 343–391.

[1] Collinge has, however, found rudimentary scales in the skin of the recent *Polydon folium* (*Journ. Anat. and Phys.*, ix. pp. 458–487), and Cope has described an allied Eocene genus, *Crossopholis*, in which minute scales are seen (*Mem. Nat. Acad. Sciences*, iii. 1886, pp. 161–163).

[2] Dr. Smith Woodward also refers the singular Belonorhynchidæ of the Trias to the same sub-order on account of the excess of the number of the dermal rays of the dorsal and anal over that of their supporting ossicles, even although the tail is here abbreviate diphycercal.

Then if we refer to the tail of *Lepidosteus* itself we shall observe how few are its rays and how evident it is that we have here to do only with the lower lobe of the original palæoniscoid caudal fin. For a convincing corroboration of this we have only to look at the tail of the embryo *Lepidosteus* as described and figured by Prof. A. Agassiz to see that it in reality passed through an Acipenseroid stage, and the last we see of the upper lobe of this tail is in the form of a filament which projects from the top of the original lower lobe and then disappears.

Again, in these Lepidosteid forms we have a repetition of the same tendency for the thick rhombic, peg-and-socket articulating scales to become rounded and imbricating as we saw in the Crossopterygii and again in the Palæoniscidæ. So, for instance, in *Caturus*, which has been shown by Dr. Smith Woodward to resemble *Eugnathus* so closely in structure, the scales are deeply overlapping, and most of them "cycloidal" in shape. To such an extent does this go that in the recent *Amia*, whose skeletal structure so clearly shows it to belong to this group, the rounded scales are so thin and flexible that after it was removed from the Clupeoid family, or Herrings, and placed among the "Ganoids" it was considered to be the type of a distinct sub-order of "Amioidei." Ten years ago, however, Dr. Beard came to the conclusion, from anatomical and embryological data, that this division could no longer be maintained, and that the Amioids must in fact be united with the Lepidosteids.[1] Dr. Smith Woodward has, therefore, in the third volume of his catalogue, done well to reduce the "Amioidei" to the rank of a family, including also the Jurassic genera *Liodesmus* and *Megalurus*, and to place this family close to the Eugnathidæ.

As the Asipenseroids dwindled away after the close of the great Palæozoic era, and are now scantily represented only by the degenerate paddle-fishes and sturgeons, so the Lepidosteid series, flourishing greatly in the Trias and Jura, in their turn declined in the Cretaceous, and in the Tertiary period became about as much a thing of the past as they are now, the North American *Lepidosteus* and *Amia*, of which remains of extinct species have also been found in Eocene and Miocene rocks, only remaining. These two genera can, however, hardly be called "degenerate."

But that the fishes which succeeded the Lepidosteids in populating the seas and rivers of the globe were evolved from them there can be no reasonable doubt, while it is equally clear that they branched off at an early period, as already in the Trias we find the first representatives of the order of Isospondyli, which contains our familiar Herrings, Salmonids, Elopids, Scopelids, &c. For Dr. Smith Woodward has not only definitely placed the Jurassic Leptolepidæ and Oligopleuridæ in the Isospondyli, but also the Pholidophoridæ, which appear in the Trias and extend to the Purbeck. And it is of special interest that in the Pholidophori the scales are still brilliantly ganoid and mostly retain the peg-and-socket articulation, while in the allied Leptolepidæ, although they have become thin and circular, a layer of ganoine mostly remains.

With the Isospondyli we now get fairly among the bony fishes of modern type—Teleostei as we used to call them—to which other sub-orders are added in Cretaceous and Tertiary times, and which in the present day have assumed an overwhelming numerical preponderance over all other fishes. The prevalent form of scale among these is thin, rounded, deeply imbricating, and with the posterior margin either plain (cycloid) or serrated (ctenoid). But that these "cycloid" and "ctenoid" scales are modifications from the rhombic osseous "ganoid" type we cannot doubt after what we have seen. It is indeed strange that the same tendency to the change of rhombic into circular overlapping scales should have occurred independently in more than one group.

For reasons given at the beginning, and also because I fear I have already exceeded the limit of time usually allotted to such an Address, I must now stop.

But in conclusion I may allude to a well-known fact regarding the tail of these modern fishes, the bearing of which on the doctrine of Descent is sufficiently clear and has long been recognised.

We have seen that the completely heterocercal tail of the typical Acipenseroid becomes, by abortion of the upper lobe and shortening of the axis, the semi-heterocercal one of the Lepidosteids, in most of which, however, the want of symmetry is still perceptible externally by a short projection or "sinus" of scales which is directed obliquely upward at the beginning of the top of the fin. In the ordinary bony fishes and in some Lepidosteids also the caudal fin becomes likewise symmetrical, as seen from the outside; generally also bilobate, though the upper lobe is not that of a Palæoniscid or Sturgeon. This condition of tail has been long known as "homocercal." But in many such homocercal tails, when we dissect away the skin and soft parts, the upward bend of the vertebral axis is revealed, and in some, as in the Salmon, the extremity of the vertebral axis is continued as a cartilaginous style among the rays near the upper margin of the fin. But there are many others, such, for instance, as the peculiarly specialised group of Pleuronectidæ or flat fishes, in which the skeleton of the caudal extremity *looks* quite symmetrical, but yet in the embryo the extremity of the notochord is seen to have an upward bend, showing that the homocercal tail is indeed a specialisation on the old heterocercal one. It is strange that though this embryological fact was long ago pointed out by Agassiz, and though he noted its great interest in connection with the prevalence of heterocercy among the Palæozoic fishes, yet he remained to the end an opponent of evolution. But this is just one of these instances in which Phylogeny and Ontogeny mutually illustrate each other. Why, otherwise, should the tail of the embryo stickleback or flounder be heterocercal?

Incompletely as I have treated the subject, it cannot but be acknowledged that the palæontology of fishes is not less emphatic in the support of Descent than that of any other division of the animal kingdom. But in former days the evidence of fossil ichthyology was by some read otherwise.

It is now a little over forty years since Hugh Miller died: he who was one of the first collectors of the fossil fishes of the Scottish Old Red Sandstone, and who knew these in some respects better than any man of his time, not excepting Agassiz himself. Yet his life was spent in a fierce denunciation of the doctrine of evolution, then only in its Lamarckian form, as Darwin had not yet electrified the world with his "Origin of Species." Many a time I wonder greatly what Hugh Miller would have thought had he lived a few years longer, so as to have been able to see the remarkable revolution which was wrought by the publication of that book.

The main argument on which Miller rested was the "high" state of organisation of the ancient fishes of the Palæozoic formations, and this was apparently combined with a confident assumption of the completeness of the geological record. As to the first idea, we know of course that evolution means the passage from the more general to the more special, and that although as the general result an onward advance has taken place, yet specialisation does not always or necessarily mean "highness" of organisation in the sense in which the term is usually employed. As to the idea of the perfection of the geological record, that of course is absurd.

We do not and cannot know the oldest fishes, as they would not have had hard parts for preservation, but we may hope to come to know many more old ones, and older ones still, than we do at present. My experience of the subject of fosil ichthyology is that it is not likely to become exhausted in our day.

We are introduced at a period far back in geological history to certain groups of fishes some of which certainly are high in organisation as animals, but yet of generalised type, being fishes and yet having the potentiality of higher forms. But, because their ancestors are unknown to us, that is no evidence that they did not exist, and cannot overthrow the morphological testimony in favour of evolution with which the record actually does furnish us. We may therefore feel very sure that fishes, or "fish-like vertebrates," lived long ages before the oldest forms with which we are acquainted came into existence.

The modern type of bony fish, though not so "high" in many anatomical points as that of the Selachii, Crossopterygii, Dipnoi, Acipenseroidei and Lepidosteoidei of the Palæozoic and Mesozoic eras, is more specialised in the direction of the fish proper, and, as already indicated, specialisation and "highness" in the ordinary sense of the word are not necessarily coincident. But ideas about these things have undergone a wonderful change since those pre-Darwinian days, and though we shall never be able fully to unravel the problems concerning the descent of animals, we see many things a great deal more clearly now than we did then.

---

## SECTION F.

### ECONOMIC SCIENCE AND STATISTICS.

ABRIDGED FROM THE OPENING ADDRESS BY MAJOR P. G. CRAIGIE, V.P.S.S., PRESIDENT OF THE SECTION.

OF all statistical work the enumeration of the units of population must ever take the foremost place, and on the eve of the census to be taken before many more months have passed a reference to that great impending task could hardly be omitted on this occasion. In common with all students of the machinery of census-taking, I am sure I echo the feelings of the Section—as I do those of the Royal Statistical Society, who have long laboured in this direction—in deeply regretting that the first census of the twentieth century is not to possess the distinction many had hoped to see conferred upon it of being by preliminary announcement—as I hope it may prove to be in ultimate fact—the first of a series not of decennial but of quinquennial countings of the people.

The growing complexity of social conditions and speed of life in all its functions at the present date, contrasted with the leisurely movements of a hundred years ago, would alone and amply justify a more frequent stock-taking of the inhabitants of Great Britain than has been the practice in the past. The practical wants of our much multiplied system of local government cannot fail, I believe, ere long to bring about the granting of an intermediate numbering, even if for the moment other considerations overrule the more academic pleas of statisticians for this reform, or the arguments, sound as I believe them to be, for a permanent Census Office, a permanent Census Act, and a trained and continuous Census Staff, to whom preparation of the machinery beforehand and detailed elaboration of the results after the actual census year might with real economy be entrusted.

Although the proposal which has been before the International Statistical Institute in one form or another for a sychronous "world's census," at the moment of passing from one century to another, is hardly likely, for administrative reasons, and in view of the previous fixtures of the great census-taking Governments of the earth, to be literally realised, the dates of the great countings of the nations will nevertheless come sufficiently close for all practical comparisons. The great Russian enumeration, on the success of which M. Troinitsky is so heartily to be congratulated, is not yet long accomplished. The twelfth census of the United States is now being taken. The Scandinavian inquiry coincides with the century's end, the Italian and the Spanish censuses are already overdue, and both France and England take their count within a few months after the twentieth century has begun.

Attempts to utilise statistical data, to determine the relative development of agriculture in different parts of the world and at different periods of time, are sometimes made with regard solely to what is described as the world's aggregate of one or two leading individual products as typical as the rest; or, again, one or two typical countries, or at least countries where the available information is more complete than elsewhere, are chosen, and the course of development or decline of their crop areas or the several descriptions of their animal produce is traced and compared.

Certain obvious objections, which it is well to recognise, impede the student of figures who resolves to proceed on the first of these methods. At the outset he is arrested by embarrassment attending the choice of what single products are to be held as representative of agricultural outturn. The most usual of all selections is that which restricts inquiries to the case of wheat. This course appears to be rendered, comparatively speaking, easy, as more has probably been written and more statistics, official or unofficial, theoretical or commercial, actual or imaginary, have been compiled with regard to this bread grain than for any other crop. But it is time we recognised that wheat has too much and too exclusive attention directed to it as a type of agricultural production. Very widely as it is undoubtedly used in the form of bread, even as food its place is occupied at one time or another, and in one country or another, by other substitutes, and its cultivation, is, after all, not the employment which demands the most attention and most skill at the hands of the agriculturist. Not only do rye and even maize serve as substitutes or supplements in feeding man, but other crops, such as oats, barley, millet, rice, and so on, have claims to greater notice than they receive, and play a direct as well as indirect part in providing food. Cotton, flax and wool are other typical products, the use of which for clothing is all-important to an enormous population, and the extension or retrogression of such crops deserves some of the attention of the agricultural statistician. Tea, coffee, wine, spirits and beer are, it is not to be forgotten, agricultural products in one clime or another, either directly or indirectly; and crops so important as sugar or tobacco are almost to be classed as necessaries of existence. Of yearly growing importance is it also, in these days, when the animal portion of our food supply bulks so much more fully than before in the daily rations of populations as they grow in wealth and increase in consumptive power, that we should closely follow the fluctuations in the live stock maintained for food and learn the teaching of the agricultural returns on the manufacture of beef, of mutton, of pig meat, or of milk.

Although the attempt to grasp the relative magnitude of the agricultural production of one State as compared with another, or to note the growth or decline of its prominence in the cultivation of particular staples, or the manufacture of particular kinds of human food, is always an enterprise of difficulty in existing statistical conditions, it is one which has fascination for many classes of economists and politicians. If attempted at all, it is well to recognise that there are inevitable dangers in the task, and that if any figures are relied on as conclusive their meaning must be interpreted by some knowledge of the demographic conditions of each State and its geographical, climatic and agricultural circumstances.

Taking a few of the most conspicuous products of the soil, it will generally be found that a very few leading States are so particularly identified with one or other type of production that the examination of their records are therefore available as guides to the course of a single crop.

Probably quite two-thirds of the cotton of the world is grown in the United States alone, where the surface so employed reaches 25,000,000 acres as compared with under 9,000,000 acres in British India, the next largest cotton-growing region of which statistical record exists. In wool the produce of the Australasian Colonies of Great Britain—with flocks which still exceed 100,000,000 head—makes much the largest contribution to the total. In rice, so far as statistics carry us, our Indian possessions head the list of producers. In hops the English crop still probably exceeds the German in production, although the latter with larger area closely contests the place. In tobacco, while the acreage apparently employed in British India is nearly double the 595,000 acres in the United States, no other country in our statistical records comes within one-seventh of the American area. The vineyards of Italy are returned as covering 8,500,000 acres, and those of France 4,300,000 acres, while those of Austria and Hungary, next in magnitude, cover but a seventh part of the last-mentioned figure. Russia bulks largely as a grower of flax, and alone shows a whole third of the area of barley recorded in all the countries which supply returns, and if in the case of potatoes the Russian acreage is not very different from that of Germany the total production of the latter empire reaches the largest aggregate of any single country.

If the subject of inquiry be the place of wheat-growing in the world at one date or another, it would not be to the older European countries, other than Russia at all events, we should turn to see where the surface so utilised was extending. Reckoned by the percentage of her cereal area which she still devotes to wheat, France, with 47 per cent. under the crop, or Italy, with 55 per cent., would naturally be selected as typical wheat-growers; but both are practically in a stationary or, collectively, even in a slightly retrograding position. It is on the other side of the Atlantic where the most noteworthy movements have occurred. In comparatively new exporting countries, such as Argentina and Canada, though the statistics from neither are complete, wheat areas still extend, and that of the United States, though fluctuating with great sensitiveness under varying price conditions, and moving from one centre to another westward or northwestward across the American continent, is now reported as covering 44,600,000 acres. This total, it must be allowed, whatever views may be held as to future progress, makes the United States a typical grower of this particular cereal, to which it gives an importance second only to the still more extensive product of American soil, to which we give the name of maize, but to which alone in American parlance is allowed the title of corn.

The leading changes in the production of typical crops as measured by the acreage, and the stock of cattle, sheep and swine recorded at or near the commencement, the middle, and the close of the past thirty years, may be contrasted for exporting countries with expanding populations and growing agriculture, and in countries where these conditions are absent, or in a typical consuming centre like our own country. Relying on the agricultural returns of the United States, a table could be constructed, as under, for three dates within the past thirty years which furnish the following indication of agricultural changes:—

| United States | 1870 | 1885 | 1899 |
|---|---|---|---|
| Population, in million persons ... | 38·6 | 56·1 | 76·0 |
| Area under maize, in million acres | 38·6 | 73·1 | 82·1 |
| Area under wheat ,, | 19·0 | 34·2 | 44·6 |
| Area under oats ,, | 8·8 | 22·8 | 26·3 |
| Area under cotton ,, | 9·9 | 18·3 | 25·0 |
| Cattle (million head) ... ... | 25·5 | 43·8 | 43·9 |
| Sheep ,, ... ... | 40·9 | 50·4 | 41·9 |
| Swine ,, ... ... | 26·8 | 45·1 | 38·7 |

In 1870 the United States held, it would thus appear, a population of 38,600,000, and grew an acre of maize for each unit of the population, and an acre of wheat for every two persons, and somewhat more than an acre of cotton for every four. At this period the surplus exported to other nations, it may be added, represented two-thirds of the cotton, rather more than one-fifth of the wheat, but less than one per cent. of the maize.

In 1885 the population had augmented to an estimated total of 56,000,000, or by 45 per cent. The area under the crops above quoted had meantime been extended in nearly twice this ratio. The United States exported still about two-thirds of the cotton grown; the wheat export was slightly greater in proportion to the product than before, or 26 per cent.; while nearly 3 per cent. of the maize crop found a market abroad.

The population of the States is now estimated to have risen to 76,000,000, or twice what it was thirty years ago, although the census has yet to say if this calculation has been realised. The cultivation of maize had meantime reached 82,000,000 acres, wheat was reported to cover 44,000,000 acres, and cotton 25,000,000 acres, while the foreign market received 65 per cent. of the cotton, 33 per cent. of the wheat, and now as much as 9 per cent. of the maize grown on these areas.

In none of these cases, it will be noted, has the area under crop failed to increase, but in all the rate of increase was distinctly slower in the second than in the first half of the period. If time sufficed to trace the annual course of movement between the contrasted dates, it might be well remembered that from 1871 onward to 1889, with only a single slight check in 1887, the growth of the maize acreage has been continuous. From 1889 to 1894 fluctuations were reported yearly, ending in the latter year at a total acreage no higher than that of 1880, but returning again in a single year, if the record can be trusted, to the highest point reached. The wheat acreage movement has been more irregular, and the latest figures are complicated by the admitted corrections which were made to an amount of 5,000,000 acres for too low previous estimates in 1897. Allowing for this, the regular upward movement of the wheat acreage was apparently checked in 1880, and has only begun again since 1898 under the stimulus of higher prices in that year.

In live stock the development would seem to have been arrested altogether between 1885 and the end of the century in the case of cattle, and turned into an absolute decline in the number of sheep and swine, although in the fifteen years before 1885 cattle had increased more than 71 per cent., swine 74 per cent., and sheep 25 per cent. As a matter of fact the maximum number of cattle was reached in 1892, when the numbers were 54,000,000, or ten millions more than at present, the stock of swine declining in a still greater ratio from the same year, and sheep declining and rising again in the separate periods between 1883 and 1889, and between 1893 and 1897. If the ratio under each head to population is considered, it would appear that the United States possessed 661 cattle for every 1000 of her citizens in 1870. This was raised to 829 per 1000 persons in 1885, while the ratio now has fallen again below the starting-point, or to 604 per 1000 persons. Sheep have fallen in the thirty years from 1060 in 1870 to 880, and now to 537 head only per 1000 inhabitants. These remarkable changes are worthy of note in connection with the exports of living animals and animal products, which last have been maintained at a still higher level than before.

Turning to a country of nearly stationary population, provided for in the main from its own agricultural produce with only slight assistance from abroad, a like contrast for the beginning, the middle, and the end of the period under review will give roughly the results shown below. Here, although we are provided with an annual figure, the start has to be made after the Franco-German war with the data two years later, or in 1872. (For table, see below).

Thus in France, where wheat-growing has always had such a predominance among the cereals, the area is neither increasing nor diminishing. The total of 17,000,000 acres falls, however, somewhat short of the provision of an acre to two persons, which held good in the United States; but this is more than corrected by the higher average yield, which is nearly 5 bushels per acre greater in France than in America. Taking wheat and rye together, there are a million acres less of bread corn grown in France than there was when her slow-moving population was two millions smaller, or less than 58 acres to 100 persons now as against 60 acres to the 100 twenty-eight years ago.

| France | 1872 | 1885 | 1899 |
|---|---|---|---|
| Population, in million persons ... | 36·1 | 38·2 | 38·5 |
| Area under wheat, in million acres ... | 17·1 | 17·2 | 17·1 |
| Area under oats ,, ... | 7·9 | 9·1 | 9·7 |
| Area under rye ,, ... | 4·7 | 4·1 | 3·6 |
| Area in vineyards ,, ... | 6·5 | 4·9 | 4·3[1] |
| Cattle (million head) ... ... | 11·3 | 13·1 | 13·4[1] |
| Sheep ,, ... ... ... | 24·6 | 22·6 | 21·3[1] |
| Swine ,, ... ... ... | 5·4 | 5·8 | 6·2[1] |

[1] 1898.

The changes which the last quarter of the nineteenth century has seen in the leading features of French agriculture may be easily summarised. The population of 1872 but little exceeded 36,000,000, that of 1885 reached 38,000,000, and the latest data only bring it up to little over 38,500,000. The wheat-growing area remains, it would appear, under all conditions practically at 17,000,000 acres, the only break to the general uniformity of the cultivation of this cereal (with which the returns include spelt) occurring in the season of 1891, when, under exceptional climatic conditions, only 14,000,000 acres were harvested.

There is one typical French agricultural product—wine—which has materially declined under circumstances which are well known. The vineyards of 1872, which were reported as covering 6,500,000 acres, are now returned as less by a third of that area, and covering 4,300,000 acres only.

In cattle a material growth up to 1885, but a very small increase since that year, is reported; while if sheep, as in all European countries, are fewer, the fall is less than in Germany, and it is most marked in the first half of the period. Swine in France have steadily increased. As regards the cattle, it may be noted that France had 313 cattle to each 1000 of her people in 1872, 345 in 1885, and 352 per 1000 now. Of sheep the number per 1000 is 560, against 681 at the earlier date.

Treating a few of the distinctive points of our own agriculture in the same way at the beginning, middle, and end of the past thirty years, the statistics of the United Kingdom would give these results:—

| United Kingdom | 1870 | 1885 | 1899 |
|---|---|---|---|
| Population, in million persons ... | 31·2 | 36·0 | 40·7 |
| Area under wheat, in million acres | 3·8 | 2·6 | 2·1 |
| Area under oats ,, ,, | 4·4 | 4·3 | 4·1 |
| Area under other corn crops ,, | 3·6 | 3·1 | 2·6 |
| Cattle (million head) ... ... | 9·2 | 10·9 | 11·3 |
| Sheep ,, ... ... ... | 32·8 | 30·1 | 31·7 |
| Swine ,, ... ... ... | 3·7 | 3·7 | 4·0 |

Here the most striking contrast with France is in the growth of population. From being a country with 5,000,000 fewer inhabitants the United Kingdom is now one actually greater by 2,000,000 persons than is France. This is an increase of more than 30 per cent., while the surface under wheat has heavily fallen, the main loss occurring under circumstances which have been amply discussed between 1879 and 1895. With some revival, as in America, consequent on an improvement of price in recent years, the slight apparent decline I have shown in the cultivation of oats is in fact confined to Ireland, the area in Great Britain being greater than at the beginning of the period. The cattle stock of the United Kingdom is increased by some 23 per cent., and the swine by about 8 per cent., while our flocks of sheep have been maintained at a level far exceeding that of other European States, and distinctive in a peculiar manner of the agriculture of Great Britain, for they still represent, as it appears, on the average 400 sheep to every 1000 acres of land, against 164 in France, 81 in Germany, 32 in Belgium, and 17 in the United States.

Passing to a comparison with another great country, which, like the United States, is a typical exporter of more than one form of agricultural produce, it may be asked how far the available statistics of Russia allow such information to be furnished. For the earliest of the three years contrasted the dates from the Russian empire are meagre and unsatisfactory. Poland must be excluded as blank in our statistics at that time, while as regards animals no figures at all would appear to have been made public for any of the last twelve years. With such qualifications as these, the available data for the nearest year in the larger crops stood as under :—

| Russia in Europe (*ex* Poland) | 1870 | 1885 | 1899 |
|---|---|---|---|
| Population, in million persons ... | 65·7 | 81·7 | 94·2 [3] |
| Area of rye, in million acres ... | 66·4 [1] | 64·6 | 63·4 |
| Area of wheat ,, ... | 28·7 [1] | 28·9 | 38·0 |
| Area of oats ,, ... | 32·8 [1] | 34·9 | 36·1 |
| Area of other cereals, in million acres ... ... ... ... | ? | 31·4 | 34·2 |
| Cattle (million head) ... ... | 22·8 | 23·6 [2] | (24·6) [4] |
| Sheep ,, ... ... | 48·1 | 46·7 [2] | (44·5) [4] |
| Swine ,, ... ... | 9·1 | 9·4 [2] | (9·2) [4] |

[1] In 1872. [2] In 1883. [3] Census of 1897. [4] In 1888.

Thirty years ago the population of European Russia, *ex* Poland, would appear from such data as we possess to have been estimated in round numbers at under sixty-six million persons. It is given as somewhere about eighty-two millions in 1885, and according to the recent census it is ninety-four millions now. The bread corn of the country continues to be much more largely rye than wheat, and the area in the year 1872, for which statistics are available, occupied by the former crop was practically an acre to the person, or in all 66,400,000 acres, less than half an acre per inhabitant, or 29,000,000 acres, being under wheat. The combined surface devoted to these two bread grains together was thus 95,000,000 acres in the aggregate, or 145 acres to every 100 persons.

Fifteen years later, when the population was apparently greater by 16,000,000 persons, or 24 per cent., the statistics of rye acreage indicate 2,000,000 acres less than before, or 64,600,000 acres. The wheat acreage, if the official data be accepted, was little if at all in excess of the 1872 figure, the rye and wheat together roughly giving 115 acres to 110 persons. The suggestion of this decline, while the exports of both grains were maintained or extended, affords an opportunity for closer inquiry into the basis of the published returns which are received from that country.

But carrying the review of the official figures further, the very latest data for this section of the Russian territory would appear to indicate a yet further shrinkage in the acreage of rye, but accompanied now, as was apparently not the case until lately, by a considerable increase in land under wheat. The total of this cereal is now put as high as 38,000,000 acres, but the net available area of bread-stuffs, although brought up to 101,000,000 acres, represents a still diminishing ratio to population, or 107 acres to every 100 persons. Moreover, as Russia must be regarded as growing both wheat and rye for export as well as consumption, the larger proportions of her acreage which is employed in feeding a non-Russian population deserve to be specially marked in this connection, when the low yields of both cereals are remembered.

Whether the foregoing figures do indeed represent the facts of each period is, I think, a worthy object of inquiry for some of our younger statisticians, and it is a problem one would like to see solved as regards this particular country before venturing on any too confident conclusion as to what is the real meaning of the changes of the past, and what may be the future position in regard to the growth of bread-stuffs and the growth of population in the world as a whole.

Calculations, however, such as those just quoted cannot fail to remind the student how very different in productive power the "acre" of wheat may be, and is, in different countries. Assuming that we take the existence of 38,000,000 acres as reported of wheat land in Russia in Europe (*ex* Poland) to be proved, a comparison of the estimated yields shows that such an area represents less than 12,000,000 acres of the productive power we are accustomed to in Great Britain. So, too, for the vast wheat area of the United States, it takes two and a third acres to produce what is now our average yield in this country. Three Indian or three Italian acres of wheat of the calibre now in use would in the same way be required to supply the number of bushels that a single acre of our soil in the climate we enjoy, and worked under the system of farming that we practise here, would in ordinary seasons produce. In other extensive areas of wheat-growing the yields, though greater than the above, are very considerably below our own, the Austrian, Hungarian and French yields standing at 16, 17 and 18 bushels respectively, against the 30 bushels which is apparently the average yield of the last five years in the United Kingdom. Only when we come to very small total areas do we find instances where the average wheat yields approach or over any considerable periods exceed our own. When Denmark, for example, is referred to as reaching 42 bushels per acre in the season of 1896, it is not to be forgotten that only a minute area of selected land, in this case only 84,000 acres, is devoted to this cereal. Results realised on this small scale can hardly be spoken of as an average in contrast with those of countries where millions of acres are grown, and can usually be paralleled in some sections of the bigger country.

Nor should it be forgotten, if the agricultural position of one State be compared with another, how widely the conditions of different parts vary from the picture presented by the average figures credited to the State as a unit, and how often sections of one country differ more from each other agriculturally than from the country with which they are contrasted. Within the United Kingdom alone we are, or ought to be, familiar with essential local differences of this type, which have to be kept in mind. Even in respect of the relative density of population and the number of mouths to be sustained in a given area, it may be quite correct to describe every 1000 acres in the United Kingdom as carrying on their surface on the average 519 persons, but it may be remembered with advantage that, considered geographically apart, Scotland, for example, is a country of but 220 persons, and Ireland of but 219, to the 1000 acres of area.

Such a position suggests that it might be fair to draw our agricultural comparisons between Scotland or Ireland as units of area, and such a country as Denmark, where the population is 248 to the 1000 acres. Thus one-third of the cereal area of England is still devoted to the growth of wheat, while Denmark has but 3 per cent. so occupied, thereby resembling Scotland or Ireland, where some 4 per cent. only of the corn is wheat. Similarly, on this population basis, Austria with 320 persons, or Switzerland with 312, to the 1000 acres may be not inappropriately classed with Wales, where the density is 345. In particular, an examination of the live stock maintained by each 1000 acres of the surface in all these cases affords parallels and contrasts which are both interesting and instructive. (For table, see p. 512.)

Thus Wales bears easily the palm as regards the total stock of sheep carried, while Ireland, with a population practically bearing a similar ratio to that of Scotland to her surface, has more than three times as dense a stock of cattle and more than eight times as many pigs, although not much more than half as many sheep to the 1000 acres. Although beaten as regards the number of pigs maintained on a given area by Denmark and by Hungary, Ireland's cattle are more than twice as numerous relatively as those of France, where the population is not so very different in proportion to the soil.

| Country | Per 1000 Acres of Total Area | | | |
|---|---|---|---|---|
| | Persons | Cattle | Sheep | Swine |
| Ireland ... ... ... ... | 219 | 217 | 207 | 61 |
| Scotland ... ... ... | 220 | 64 | 390 | 7 |
| Hungary ... ... ... | 232 | 85 | 102 | 92 |
| Denmark ... ... ... | 248 | 186 | 115 | 88 |
| France ... ... ... ... | 293 | 103 | 164 | 48 |
| Switzerland ... ... ... | 311 | 132 | 27 | 57 |
| Austria ... ... ... ... | 320 | 117 | 43 | 48 |
| Wales ... ... ... ... | 345 | 147 | 685 | 50 |

Among countries where the areas are still greater in proportion to the resident population it may not be without interest to group together—as regards their present density—persons, cattle, sheep and swine.

| Countries | Per 1000 Acres of Total Area | | | |
|---|---|---|---|---|
| | Persons | Cattle | Sheep | Swine |
| New South Wales ... | 7 | 10 | 221 | 1 |

[1] In 1890.

[2] In 1888.

Such figures serve to emphasise the vast difference between the flocks maintained in our Australasian Colonies and the other countries in this group.

The animal wealth of England by herself, omitting the Celtic fringes above quoted, may be compared with a nearer competitor. Belgium has 893 persons to 1000 acres, England 925; and Belgium has 195 head of cattle and 160 head of swine, but only 32 sheep, on an average area of this size in her little kingdom, against 144 cattle, 64 pigs, and as many as 488 sheep in England. Were the comparison to be made more closely yet, the cattle stock of Belgium agrees closely in point of density with, say, the particular division of our area comprising the north-western counties of England, which have 194 cattle to 1000 acres, or considerably more than the great butter-exporting country of Denmark, and at least a very close approach to the 197 head per 1000 acres which are to be found in the fat pastures of the Netherlands.

These limited comparisons on single points of agricultural production in single countries do not, I know, satisfy the demands which are often made for world-wide surveys and comparisons on a larger scale. I confess I somewhat distrust the strength and due coherence of the statistical bricks on which these heroic conclusions are built up. It is most usual in corn trade journals, and the practice is sometimes followed in serious debate and reproduced in the year-books of the United States Government, to give a yearly picture of at least the world's wheat crop. For the close comparison of one season with another much must depend on the sufficiency of the weakest item in the account, and weakness is sure to creep in somewhere when crops are estimated on varying systems, at different dates, and on authorities of unequal value. The definitions adopted by one calculator as to the limits of the "world" vary from those of another, and commercial estimates, as they are called, may be, at the discretion of the computer, substituted for or adopted in the absence of official data, so that the guesses at a single country's harvest may differ more widely from each other than would account for the total margin between one year's aggregate supply and another, to the confounding of satisfactory conclusions as to what is really happening. Last but not least of the obstacles to uniform grouping of harvests in complete years—ending as these years do at different periods—is the fact, not to be overlooked, that wheat harvests are being gathered somewhere in every month in the twelve.

One is driven back then to the attempt to rest opinions on the growth of one form of culture or another on recorded acreage, rather than assumed production. Yet even here a good illustration of the difficulty of any extensive compilation may be found in the tentative memorandum Sir Robert Giffen put before the last Royal Commission on Agriculture as indicating, with many necessary reservations and qualifications, the relative movements of grain area, live stock, and population in the twenty years before 1893. Briefly, the earlier totals brought into conjunction for this purpose were made up, as regards the population figures taken to represent the starting-point of 1873, from the statistics of groups of countries and colonies at dates for the most part about 1871-3, but in some instances ranging back to 1866 and on to 1881, and aggregating 365,800,000 persons. Against these were set a total of 461,800,000 persons, enumerated, for the most part, about 1890-93, but in a few instances, where later data were wanting, going back to 1880-88, the growth of population between the totals being 26 per cent.

The acreage about 1873 and about 1893, contrasted with these figures, included wheat, rye, barley and oats, but not maize—a larger crop than any of the last three. The countries contrasted were limited necessarily by the extent of information, and the list did not include all of which the population was accounted for, the increases per cent. being 28 per cent. in the case of oats, 19 per cent. in the case of wheat, 5 per cent. in the case of barley, with a decrease of 5 per cent. in rye. It should be observed, however, that the calculation as to the increase of wheat would have been much closer to that of population had not a very large area, nearly stationary in amount, been credited to India and Japan at both dates; the local population of these Asiatic countries being disregarded as, generally speaking, non-wheat-eating.

It was only as an outline pointing the direction in which inquiry might be useful that Sir Robert Giffen called attention to these figures, which, as he acknowledged, were of the roughest possible description, and rather suggestive of a closer inquiry, which should take account of the difference between the consumptive power of the countries aggregated, the varying productive power of nominally equal areas of surface, and the varying type of live stock maintained.

If the wheat acreage table, in the memorandum referred to, is examined in detail, a very effective picture of the difficulty of exact comparison as between any two given dates is incidentally presented. Out of twenty-four countries enumerated (including Canada and Australasia as units) a twenty or twenty-one years' comparison is only really effected in five cases—Russia, the United States, France, United Kingdom and Australasia. In five other instances the period dealt with is only from seventeen to eighteen years; in three other cases only fourteen or fifteen years. In Canada, Egypt and Denmark, the comparison will be found to be more limited still, and only to cover eleven or twelve years; while in the Argentine Republic, where the recent expansion of wheat-growing has been prominent, the available statistics allowed only of a comparison of two periods, no more than nine years apart. For seven other countries the wheat acreage was necessarily either omitted or inserted as presumably the same as both the earlier and the later date. Had the retrospect been confined to the cases where a twenty or twenty-one years' comparison was possible—and these, after all, included the most important and typical wheat-growing communities—the increase would have stood, not at 19, but at 24 per cent., or scarcely below that of the growth of population generally. This result is reached without taking account of any South American figures, where the increase of area is relatively much greater, or of those of India, where the comparison is difficult and the acreage growing but slightly. But, further, it is to be remembered that if the comparison of the memorandum were to be continued up to 1899, instead of stopping at 1893, the figures would have shown that wheat-growing had apparently made a new start in the five important countries for which the long comparison was possible, as many million acres having been added in the past six years as in the whole preceding twenty—a result which may afford much occasion for suspending our final judgment and no little warning of the danger of single year contrasts.

Since the above calculations were before the Commission there has been an extension of 10,000,000 acres in the official estimates of wheat areas in the United States, and 5,400,000 acres in Russia, while, although official details are still wanting beyond 1895 for Argentina, nearly 3,000,000 acres more were in that year accounted for in that republic; and there is an impression, apparently well founded, that by the present time the total may have reached 8,000,000 acres, or nearly five million acres more than the final figure in Sir Robert Giffen's calculation. If anything like 20,000,000 acres have thus been added to the wheat-growing surface of the globe in the last five or six years, which these further figures suggest, even if no correction be made for the Indian quota, there may be much less difference than was suggested in the memorandum between the growth of population and wheat-growing.

Without attempting in any way to controvert what was one of the lessons of the memorandum I have been examining, as to the tendency to increase the numbers of cattle at a ratio above that of population, it has also to be remembered that the apparent 37 per cent. increase there shown between 1873 and 1893 may have to be discounted by subsequent deductions in the United States, in Australasia, and at the Cape in recent years; while it is one of the problems I have never yet seen satisfactorily answered, why in almost all old countries except our own the diminution of the stock of sheep seems continuous and remarkable. I mention these matters only, however, to suggest the amount of uncertainty which must attend the efforts to arrive at conclusions, made even by the highest authorities, on the only data which exist. If there is, as I have shown, such uncertainty still in the facts on which a conclusion could be built as to the past history of the relative growth of live stock, or of cereal culture and the supply of bread-stuffs, how much greater must the difficulty be of those who attempt, on the basis of such data, to forecast the course of events for a generation yet to come! I confess I am not intrepid enough to follow some of the conjectures which have been hazarded on this point, and can only, in concluding this address, recur once more to the prime qualifications for safe statistical deductions with which I opened my remarks—redoubled caution in handling calculations, a very guarded use of data giving records of single and isolated years, and a wise reservation in any prophetic pictures of the future of agricultural production, whether of wheat or cotton, in meat or in wool, of the contingency, always present, of altered conditions which ever and anon in the past have altered and falsified the predictions of earlier observers.

## SECTION H.

### ANTHROPOLOGY.

### OPENING ADDRESS BY PROF. JOHN RHYS, M.A., LL.D., PRESIDENT OF THE SECTION.

PERHAPS I ought to begin by apologising for my conspicuous lack of qualification to fill this chair, but I prefer, with your permission, to dismiss that as a subject far too large for me to dispose of this morning. So I would beg to call your attention back for a moment to the excellent address given to this Section last year. It was full of practical suggestions which are well worth recalling: one was as to the project of a Bureau of Ethnology for Greater Britain, and the other turned on the desirability of founding an Imperial Institution to represent our vast Colonial Empire. I mention these in the hope that we shall not leave the Government and others concerned any peace till we have realised those modest dreams of enlightenment. People's minds are just now so full of other things that the interests of knowledge and science are in no little danger of being overlooked. So it is all the more desirable that the British Association, as our great parliament of science, should take the necessary steps to prevent that happening, and to keep steadily before the public the duties which a great and composite nation like ours owes to the world and to humanity, whether civilised or savage.

The difficulties of the position of the president of this Section arise in a great measure from the vastness of the field of research which the Science of Man covers. He is, therefore, constrained to limit his attention as a rule to some small corner of it; and, with the audacity of ignorance, I have selected that which might be labelled the early ethnology of the British Isles, but I propose to approach it only along the precarious paths of folklore and philology, because I know no other. Here, however, comes a personal difficulty: at any rate I suppose I ought to pretend that I feel it a difficulty, namely, that I have committed myself to publicity on that subject already. But, as a matter of fact, I can hardly bring myself to confess to any such feeling; and this leads me to mention in passing the change of attitude which I have lived to notice in the case of students in my own position. Most of us here present have known men who, when they had once printed their views on their favourite subjects of study, stuck to those views through thick and thin, or at most limited themselves to changing the place of a comma here and there, or replacing an occasional *and* by a *but*. The work had then been made perfect, and not a few great questions affecting no inconsiderable portions of the universe had been for ever set at rest. That was briefly the process of getting ready for posterity, but one of its disadvantages was that those who adopted it had to waste a good deal of time in the daily practice of the art of fencing and winning verbal victories; for, metaphorically speaking,

> "With many a whack and many a bang
> Rough crab-tree and old iron rang."

Now all that, however amusing it may have been, has been changed, and what now happens is somewhat as follows: AB makes an experiment or propounds what he calls a working hypothesis; but no sooner has AB done so than CD, who is engaged in the same sort of research, proceeds to improve on AB. This, instead of impelling AB to rush after CD with all kinds of epithets and insinuating that his character is deficient in all the ordinary virtues of a man and a brother, only makes him go to work again and see whether he cannot improve on CD's results; and most likely he succeeds, for one discovery leads to another. So we have the spectacle not infrequently of a man illustrating the truth of the poet's belief,

> "That men may rise on stepping-stones
> Of their dead selves to higher things."

It is a severe discipline in which all display of feeling is considered bad form. Of course every now and then a spirit of the ruder kind discards the rules of the game and attracts attention by having public fits of bad temper; but generally speaking the rivalry goes on quietly enough to the verge of monotony, with the net result that the stock of knowledge is increased. I may be told, however, that while this kind of exercise may be agreeable to the ass who writes, it is not conducive to the safety of the publisher's chickens. To that it might suffice to answer that the publisher is usually one who is well able to take good care of his chickens; but, seriously, what it would probably mean is, that in the matter of the more progressive branches of study, smaller editions of the books dealing with them would be required, but a more frequent issue of improved editions of them or else new books altogether, a state of things to which the publisher would probably find ways of adapting himself without any loss of profits. And after all, the interests of knowledge must be reckoned uppermost. It is needless to say that I have in view only a class of books which literary men proper do not admit to be literature at all; and the book trade has one of its mainstays, no doubt, in books of pure literature, which are like the angels that neither marry nor give in marriage: they go on for ever in their serene singleness of purpose to charm and chasten the reader's mind.

My predecessor last year alluded to an Oxford don said to have given it as his conviction that anthropology rests on a foundation of romance. I have no notion who that Oxford don may have been, but I am well aware that Oxford dons have sometimes a knack of using very striking language. In this case, however, I should be inclined to share to a certain extent that Oxford don's regard for romance, holding as I do that the facts of history are not the only facts deserving of careful study by the anthropologist. There are also the facts of fiction, and to some of those I would now call your attention. Recently, in putting together a volume on Welsh folklore, I had to try to classify and analyse in my mind the stories which have been current in Wales about the fairies. Now the mass of folklore about the fairies is of various origins. Thus with them have been more or less inseparably confounded certain divinities or demons, especially various kinds of beings associated with the rivers and lakes of the country. They are creations introduced from the workshop of the imagination; then there is the dead ancestor, who also seems to have contributed his share to the sum total of our notions about the Little People. In far the greater number of cases, however, we seem to have something historical, or, at any rate, something which may be contemplated as historical. The key to the fairy idea is that there once was a real race of people to whom all kinds of attributes, possible and impossible, have been given in the course of uncounted centuries of story-telling by races endowed with a lively imagination.

When the mortal midwife has been fetched to attend on a fairy mother in a fairy palace, she is handed an ointment which she is to apply to the fairy baby's eyes, at the same time that she is gravely warned not to touch her own eyes with it. Of course any one could foresee that when she is engaged in applying the ointment to the young fairy's eyes one of her own eyes is certain to itch and have the benefit of the forbidden salve. When this happens the midwife has two very different views of her surroundings: with the untouched eye she sees that she is in the finest and grandest place that she has ever beheld in her life, and there she can see the lady on whom she is attending reposing on a bed, while with the anointed eye she perceives how she is lying on a bundle of rushes and withered ferns in a large cave, with big stones all round her and a little fire in one corner, and she also discovers that the woman is a girl who has once been her servant. Like the midwife we have also to exercise a sort of double vision, if we are to understand the fairies and see through the stories about them. An instance will explain what I mean: Fairy women are pretty generally represented as fascinating to the last degree and gorgeously dressed: that is how they appear through the glamour in which they move and have their being. On the other hand, not only are some tribes of some fairies described as ugly, but fairy children when left as changelings are invariably pictured as repulsive urchins of a sallow complexion and mostly deformed about the feet and legs: there we have the real fairy with the glamour taken off and a certain amount of depreciatory exaggeration put on.

Now when one approaches the fairy question in this kind of way, one is forced, it strikes me, to conclude that the fairies, as a real people, consisted of a short, stumpy, swarthy race, which made its habitations underground or otherwise cunningly concealed. They were hunters, probably, and fishermen; at any rate, they were not tillers of the ground or eaters of bread. Most likely they had some of the domestic animals and lived mainly on milk and the produce of the chase, together with what they got by stealing. They seem to have practised the art of spinning, though they do not appear to have thought much of clothing. They had no tools or implements made of metals. They appear to have had a language of their own, which would imply a time when they understood no other, and explain why, when they came to a town to do their marketing, they laid down the exact money without uttering a syllable to anybody by way of bargaining for their purchases. They counted by fives and only dealt in the simplest of numbers. They were inordinately fond of music and dancing. They had a marvellously quick sense of hearing, and they were consummate thieves; but their thievery was not systematically resented, as their visits were held to bring luck and prosperity. More powerful races generally feared them as formidable magicians who knew the future and could cause or cure disease as they pleased. The fairies took pains to conceal their names no less than their abodes, and when the name happened to be discovered by strangers the bearer of it usually lost heart and considered himself beaten. Their family relations were of the lowest order: they not only reckoned no fathers, but it may be that, like certain Australian savages recently described by Spencer and Gillen, they had no notion of paternity at all. The stage of civilisation in which fatherhood is of little or no account has left evidence of itself in Celtic literature, as I shall show presently; but the other and lower stage anterior to the idea of fatherhood at all comes into sight only in certain bits of folklore, both Welsh and Irish, to the effect that the fairies were all women and girls. Where could such an idea have originated? Only, it seems to me, among a race once on a level with the native Australians to whom I have alluded, and of whom Fraser of "The Golden Bough" wrote as follows in last year's *Fortnightly Review*: "Thus, in the opinion of these savages, every conception is what we are wont to call an immaculate conception, being brought about by the entrance into the mother of a spirit, apart from any contact with the other sex. Students of folklore have long been familiar with the notions of this sort occurring in the stories of the birth of miraculous personages, but this is the first case on record of a tribe who believe in immaculate conception as the sole cause of the birth of every human being who comes into the world. A people so ignorant of the most elementary of natural processes may well rank at the very bottom of the savage scale." Those are Dr. Fraser's words, and for a people in that stage of ignorance to have imagined a race all women seems logical and natural enough—but for no other. The direct conclusion, however, to be drawn from this argument is that some race—possibly more than one—which has contributed to the folklore about our fairies, has passed through the stage of ignorance just indicated; but as an indirect conclusion one would probably be right in supposing this race to have been no other than the very primitive one which has been exaggerated into fairies. At the same time it must be admitted that they could not have been singular always in this respect among the nations of antiquity, as is amply proved by the prevalence of legends about virgin mothers, to whom Frazer alludes, not to mention certain wild stories recorded by the naturalist Pliny concerning certain kinds of animals.

Some help to make out the real history of the Little People may be derived from the names given them, of which the most common in Welsh is that of *y Tylwyth Teg* or the Fair Family. But the word *cor*, "a dwarf," feminine *corres*, is also applied to them; and in Breton we have the same word with such derivatives as *korrik*, "a fairy, a wee little wizard or sorcerer," with a feminine *korrigan* or *korrigez*, analogously meaning a she-fairy or a diminutive witch. From *cor* we have in Welsh the name of a people called the Coranians figuring in a story in the fourteenth-century manuscript of the Red Book of Hergest. There one learns that the Coranians were such consummate magicians that they could hear every word that reached the wind, as it is put; so they could not be harmed. The name Coranians of those fairies has suggested to Welsh writers a similar explanation of the name of a real people of ancient Britain. I refer to the *Coritani*, whom Ptolemy located, roughly speaking, between the river Trent and Norfolk, assigning to them the two towns of *Lindum*, Lincoln, and *Ratae*, supposed to have been approximately where Leicester now stands. It looks as if all invaders from the Continent had avoided the coast from Norfolk up to the neighbourhood of the Humber, for the good reason, probably, that it afforded very few inviting landing-places. So here presumably the ancient inhabitants may have survived in sufficient numbers to have been called by their neighbours of a different race "the dwarfs" or *Coritani*, as late as Ptolemy's time in the second century. This harmonises with the fact that the Coritani are not mentioned as doing anything, all political initiative having long before probably passed out of their hands into those of a more powerful race. How far inland the Coritanian territory extended it is impossible to say, but it may have embraced the northern half of Northamptonshire, where we have a place-name *Pytchley*, from an earlier *Pihtes léa*, meaning "The Pict's Meadow," or else the meadow of a man called Pict. At all events, their country took in the fen district containing Croyland, where towards the end of the seventh century St. Guthlac set up his cell on the side of an ancient tumulus and was disturbed by demons that talked Welsh. Certain portions of the Coritanian country offered, as one may infer, special advantages as a home for retreating nationalities: witness as late as the eleventh century the resistance offered by Hereward in the Isle of Ely to the Norman Conqueror and his mail-clad warriors.

In reasoning backwards from the stories about the Little People to a race in some respects on a level with Australian savages, we come probably in contact with one of the very earliest populations of these islands. It is needless to say that we have no data to ascertain how long that occupation may have been uncontested, if at all, or what progress was made in the course of it: perhaps archæology will be able some day to help us to form a guess on that subject. But the question more immediately pressing for answer is, with what race outside Wales may one compare or identify the ancient stock caricatured in Welsh fairy tales? Now, in the lowlands of Scotland, together with the Orkneys and Shetlands, the place of our fairies is to some extent taken by the Picts, or, as they are there colloquially called, "the Pechts." My information about the Pechts comes mostly from recent writings on the subject by Mr. David MacRitchie, of Edinburgh, from whom one learns, among other things, that certain underground—or partially underground—habitations in Scotland are ascribed to the Pechts. Now one kind of these Pechts' dwellings appear from the outside like hillocks covered with grass, so as presumably not to attract attention, an object which was further helped by making the entrance very low and as inconspicuous as possible. But one of the most remarkable things about them is the fact that the cells or apartments into which they are divided are frequently so small that their inmates must have been of very short stature, like our Welsh fairies. Thus, though there appears to be no reason for regarding the northern Picts themselves as an undersized race, there must have been a people of that description in their country. Perhaps archæologists may succeed in classifying the ancient habitations in the North accordingly: that is, to tell us what class of them were built by the Picts and what by the Little People whom they may be supposed to have found in possession of that part of our island.

In Ireland and the Highlands of Scotland the fairies derive their more usual appellations from a word *síd* or *síth* (genitive *síde*), which may perhaps be akin to the Latin *sēdes* and have meant a seat, settlement, or station; but whatever its exact meaning may have originally been, it came to be applied to the hillocks or mounds within which the Little People made their abodes. Thus, *Aes Síde* as a name for the fairies may be rendered by mound people or hill folk; *fer síde*, "a fairy man," by a mound man; and *ben síde* by a mound woman or banshee. They were also called simply *síde*, which would seem to be an adjective closely allied with the simpler word *síd*.

But to leave this question of their names, let me direct your attention for a moment to one of the most famous kings of the fairies of ancient Erin: he was called Mider of Brí Leith, said to be a hill to the west of Ardagh, in the present county of Longford. There he had his mound, to which he once carried the queen of Eochaid Airem, monarch of Ireland. It was some time before Eochaid could discover what had become of her, and he ordered Dálan, his druid, to find it out. So the druid, when he had been unsuccessful for a whole year, prepared four twigs of yew and wrote on them in Ogam. Then it was revealed to him through his keys of seership and through the Ogam writing that the queen was in the *síd* of Brí Leith, having been taken thither by Mider. By this we are probably to understand that the druid sent forth the Ogam twigs as letters of inquiry to other druids in different parts of the country; but in any case he was at last successful, and his king hurried at the head of an army to Brí Leith, where they began in earnest to demolish Mider's mound. At this Mider was so frightened that he sent the queen forth to her husband, who then departed, leaving the fairies to digest their wrath; for it is characteristic of them that they did not fight, but bided their time for revenge, which in this case did not come till long after Eochaid's day. Now, with regard to the fairy king, one is not told, so far as I can call to mind, that he was a dwarf, but the dwarfs were not far off; for we read of an Irish satirist who is represented as notorious for his stinginess; and to emphasise the description of his inhospitable habits he is said to have taken from Mider three of his dwarfs and stationed them around his own house, in order that their truculent looks and rude words might repel any of the men of Erin who might come seeking hospitality or bring any inconvenient request. The word used for dwarf in this story is *corr*, which is usually the Irish for a crane or heron, but here, and in some other instances, which I cannot now discuss, it seems to have been identical with the Brythonic *cor*, "a dwarf." It is remarkable, moreover, that the *rôle* assigned to the three Irish *corrs* is much the same as that of the dwarf of Edeyrn son of Nudd in the Welsh story of *Geraint and Enid* and Chrétien de Troies' *Erec*, which characterises him as *fel et de put'eire*, "treacherous and of an evil kind."

By way of summarising these notes on the Mound Folk I may say that I should regard them as isolated and wretched remnants of a widely spread race possessing no political significance whatever. But, with the inconsistency characteristic of everything connected with the fairies, one has on the other hand to admit that this strange people seems to have exercised on the Celts—probably on other races as well—a sort of permanent spell of mysteriousness and awe stretching to the verge of adoration. In fact, Irish literature states that the pagan tribes of Erin before the advent of St. Patrick used to worship the *síde* or the fairies. Lastly, the Celt's faculty of exaggeration, combined with his incapacity to comprehend the weird and uncanny population of the mounds and caves of his country, has enabled him, in one way or another, to bequeath to the great literatures of Western Europe a motley train of dwarfs and little people, a whole world of wizardry, and a vast wealth of utopianism. If you subtracted from English literature, for example, all that has been contributed to its vast stores from this native source, you would find that you left a wide and unwelcome void.

But the question must present itself sooner or later, with what race outside these islands we are to compare or identify our mound-dwellers. I am not prepared to answer, and I am disposed to ask our archæologists what they think. In the meantime, however, I may say that there are several considertions which impel me to think of the Lapps of the North of Europe. But even supposing an identity of origin were to be made out as between our ancient mound-inhabiting race and the Lapps, it would remain still doubtful whether we could expect any linguistic help from Lapland. The Lapps now speak a language belonging to the Ugro-Finnic family, but the Lapps are not of the same race as the Finns; so it is possible that the Lapps have adopted a Finnish language, and that they did so too late for their present language to help us with regard to any of our linguistic difficulties. One of these lies in our topography: take for instance only the names of our rivers and brooks—there is probably no county in the kingdom that would be too small to supply a dozen or two which would baffle the cleverest Aryan etymologist you could invite to explain them; and why? Because they belong in all probability to a non-Celtic, non-Aryan language of some race that had early possession of our islands. Nevertheless it is very desirable that we should have full lists of such names, so as to see which of them recur and where. It is a subject deserving the attention of this Section of the British Association.

We have now loitered long enough in the gloom of the Pecht's house: let us leave the glamour of the fairies and see whether any other race has had a footing in these islands before the coming of the Celts. In August 1891 Prof. Sayce and I spent some fine days together in Kerry and other parts of the south-west of Ireland. He was then full of his visits to North Africa, and he used to assure me that, if a number of Berbers from the mountains had heen transferred to a village in Kerry and clad as Irishmen, he would not have been able to tell them by their looks from native Irishmen such as we saw in the course of our excursions. This seemed to me at the time all the more remarkable, as his reference was to fairly tall blue-eyed persons whose hair was rather brown than black. Evidence to the same effect might now be cited in detail from Prof. Haddon and his friends' researches among the population of the Arran Islands in Galway Bay. Such is one side of the question which I have in my mind: the other side consists in the fact that the Celtic languages of to-day have been subjected to some disturbing influence which has made their syntax unlike that of the other Aryan languages. I have long been of opinion that the racial interpretation of that fact must be, that the Celts of our islands have assimilated another race using a language of its own in which the syntactical peculiarities of Neo-Celtic had their origin; in fact that some such race clothed its idioms in the vocabulary which it acquired from the Celts. The problem then was to correlate those two facts. I am happy to say this has now been undertaken from the language point of view by Prof. J. Morris Jones, of the University College of North Wales. The results have been made public in a book on The Welsh People recently published by Mr. T. Fisher Unwin. The paper is entitled "Pre-Celtic Syntax in Insular Celtic," and the languages which have therein been compared with Celtic are old Egyptian and certain dialects of Berber. It is all so recent that we have as yet had no criticism, but the reasoning is so sound and the arguments are of so cumulative a nature, that I see no reason to anticipate that the professor's conclusions are in any danger of being overthrown.

At the close of his linguistic argument, Prof. Morris Jones quotes a French authority to the effect, that, when a Berber king dies or is deposed, which seems to happen often enough, it is not his son that is called to succeed him, but the son of his sister, as appears to have been usual among certain ancient peoples of this country; but of this more anon. In the next place my attention has been called by Prof. Sayce to the fact that ancient Egyptian monuments represent the Libyans of North Africa with their bodies tattooed, and that even now some of the Touaregs and Kabyles do the same. These indications help one to group the ancient peoples of the British Isles to whose influence we are to ascribe the non-Aryan features of Neo-Celtic. In the first place one cannot avoid fixing on the Picts, who were so called because of their habit of tattooing themselves. For as to that fact there seems to be no room for doubt, and Mr. Nicholson justly lays stress on the testimony of the Greek historian Herodian, who lived in the time of Severus, and wrote about the latter's expedition against the natives of North Britain a long time before the term *Picti* appears in literature. For Herodian, after saying that they went naked, writes about them to the following effect: "They puncture their bodies with coloured designs and the figures of animals of all kinds, and it is for this reason that they do not wear clothes, lest one should not behold the designs on their bodies." This is borne out by the names by which the Picts have been known to the Celts. That of *Pict* is itself in point, and I shall have something to say of it presently; but one of the other names was in Irish *Cruithni*, and in Welsh we have its etymological equivalent in *Prydyn* or *Prydain*. These vocables are derived respectively from Irish *cruth* and Welsh *pryd*, both meaning shape, form, or figure, and it is an old surmise that the Picts were called by those names in allusion to the animal forms pricked on their bodies, as described by Herodian and others. The earlier attested of these two names may be said to be Prydyn or Prydain, which the Welsh used to give in the Middle Ages to the Picts and the Pictland of the North, while the term *Ynys Prydain* was retained for Great Britain as a whole, the literal meaning being the island of the Picts: that is the only name which we have in Welsh to this day for this island in which we live—*Ynys Prydain*, "The Picts' Island." Now one detects this word Prydain in effect in the Greek **Πρετανικαί Νῆσοι** given collectively to all the British Isles by ancient authors, such as Strabo and Diodorus. It may be rendered the Pictish Islands, but a confusion seems to have set in pretty early with the name of the Brittanni or Brittones of South Britain: that is to say, *Pretanic*, "Pictish," became *Brittannic* or British; and this is, historically speaking, the only known justification we have for including Ireland in the comprehensive term "The British Isles," to which Irishmen are sometimes found jocularly to object.

In the next place may be mentioned the Tuatha Dé Danann of Irish legend, which cannot always be distinguished from the Picts, as pointed out by Mr. MacRitchie. The tradition about them is, that, when they were overcome in war by Míl and his Milesians, they gave up their life above ground and retired into the hills like the fairies, a story of little more value than that of the extermination of the Picts of Scotland. In both countries doubtless the more ancient race survived to amalgamate with its conquerors. There was probably some amount of amalgamation between the Tuatha Dé Danann or the Picts and the Little Moundsmen; but it is necessary not to confound them. The Tuatha shared with the Little People a great reputation for magic; but they differed from them in not being dwarfs or of a swarthy complexion: they are usually represented as fair. In the case of Mider, the fairy king, who comes in some respects near the description of the heroes of the Tuatha Dé Danann, it is to be noticed that he was a wizard, not a warrior.

Guided by the kinship of the name of the Tuatha Dé *Danann* on the Irish side of the sea and that of the Sons of *Dôn* on this side, I may mention that the Mabinogion place the Sons of Dôn on the seaboard of North Wales, in what is now Carnarvonshire: more precisely their country was the region extending from the mountains to the sea, especially opposite Anglesey. In that district we have at least three great prehistoric sites all on the coast. First comes the great stronghold on the top of Penmaen Mawr; then we have the huge mound of Dinas Dinlle, eaten into at present by the sea south-west of the western mouth of the Menai Straits; and lastly there is the extensive fortification of Tre'r Ceiri, overlooking Dinlle from the heights of the Eifl. By its position Tre'r Ceiri belonged to the Sons of Dôn, and by its name it seems to me to belong to the Picts, which comes, I believe, to the same thing. Now the name Tre'r Ceiri means the town of the Keiri, and the Welsh word *ceiri* is used in the district in the sense of persons who are boastful and ostentatious, especially in the matter of personal appearance and fine clothing. It is sometimes also confounded with *cewri*, "giants," but in the name of Tre'r Ceiri it doubtless wafts down to us an echo of the personal conceit of the ancient Picts with their skins tattooed with decorative pictures; and Welsh literature supplies a parallel to the name *Ynys Prydain* in one which is found written *Ynys y Ceuri*, both of which may be rendered equally the Island of the Picts, but more literally perhaps some such rendering as "the Island of the Fine Men" would more nearly hit the mark. Lastly, with the Sons of Dôn must probably be classed the other peoples of the Mabinogion, such as the families of Llyr, and of Pwyll and Rhiannon.

All these peoples of Britain and Ireland were warlike, and such, so far as one can see, that the Celts, who arrived later, might with them form one mixed people with a mixed language, such as Prof. Morris Jones has been helping to account for.

Let us now see for a moment how what we read of the state of society implied in the stories of the Mabinogion will fit into the hypothesis which I have roughly sketched. In the first place I ought to explain that the four stories of the Mabinogion were probably put together originally in the Goidelic of Wales before they assumed a Brythonic dress. Further, in the form in which we know them, they have passed through the hands of a scribe or editor living in Norman times, who does not always appear to have understood the text on which he was operating. To make out, therefore, what the original Mabinogion meant, one has every now and then to read, so to say, between the lines. Let us take, for example, the Mabinogi called after Branwen, daughter of Llyr. She was sister to Brân, king of Prydain, and to Manawyddan, his brother: she was given to wife to an Irish king named Matholwch, by whom she had a son called Gwern. In Ireland, however, she was, after a time, disgraced, and served in somewhat the same way as the heroine of the Gudrun Lay; but in the course of the time which she spent in a menial position, doing the baking for the Court and having a box on the ear administered to her daily by the cook, she succeeded in rearing a starling, which one day carried a letter from her to her brother Brân at Harlech. When the latter realised his sister's position of disgrace, he headed an expedition to Ireland, whereupon Matholwch tried to appease him by making a concession, which was, that he should deliver his kingdom to the boy Gwern. Now the question is, wherein did the concession consist? The redactor of the Mabinogi could, seemingly, not have answered, and he has not made it the easier for any one else to answer. In the first place, instead of calling Gwern son of Matholwch, he should have called him Gwern son of Branwen, after his mother, for the key to the sense is, that, in a society which reckoned birth alone, Gwern was not recognised as any relation to Matholwch at all, whereas, being Brân's sister's son, he was Brân's rightful heir. No such idea, however, was present to the mind of a twelfth-century scribe, nor could it be expected.

Let us now turn to Irish literature, to wit, to one of the many stories associated with the hero Cúchulainn. He belonged to Ulster, and whatever other race may have been in that part of Ireland, there were Picts there: as a matter of fact Pictish communities survived there in historical times. Now Cúchulainn was not wholly of the same race as the Ultonians around him, for he and his father are sharply marked off from all the other Ultonians as being free from the periodical illness connected with what has been called the couvade, to which the other adult braves of Ulster succumbed for a time every year. Then I may mention that Cúchulainn's baby name was *Setanta Beg*, or the Little Setantian, which points to the country whence Cúchulainn's father had probably come, namely, the district where Ptolemy mentions a harbour of the Setantii, somewhere near the mouth of the Ribble, in what is now Lancashire. At the time alluded to in the story I have in view, Cúchulainn was young and single, but he was even then a great warrior, and the ladies of Ulster readily fell in love with him; so one day the nobles of that country met to consider what was to be done, and they agreed that Cúchulainn would cause them less anxiety if they could find him a woman who should be his fitting and special consort. At the same time also that they feared he might die young, they were desirous that he should leave an heir, "for," as it is put in the story, "they knew that it was from himself his rebirth would be." The Ulster men had a belief, you see, in the return of the heroes of previous generations to be born again; but we have here two social systems face to face. According to the one to which Cúchulainn as a Celt belonged, it was requisite that he should be the father of recognised offspring, for it was only in the person of one of them or of their descendants that he was to be expected back. The story reads as if the distinction was exceptional, and as if the prevailing state of things was wives more or less in common, with descent reckoned according to birth alone. Such is my impression of the picture of the society forming the background to the state of things implied by the conversation attributed to the noblemen of Ulster. Here again one experiences difficulties arising from the fact that the stories have been built up in the form in which we know them by men who worked from the Christian point of view, and it is only by scrutinising, as it were, the chinks and cracks that you can faintly realise what the original structure was like.

Among other aids to that end one must reckon the instances of men being designated with the help of the mother's name, not the father's: witness that of the King of Ulster in Cúchulainn's time, namely Conchobar mac Nessa, that is to say, Conor, son of a mother named Nessa; similarly in Wales with Gwydion son of Dôn. Further we have the help of a considerable number of ancient inscriptions, roughly guessed to date from the fifth or sixth century of our era, and commemorating persons traced back to a family group of the kind, perhaps, which Cæsar mentions in the fourteenth chapter of his fifth book. Within these groups the wives were, according to him, in common (*inter se communes*). Take for instance an inscription from the barony of Corcaguiny in Kerry, which commemorates a man described as "Mac Erce, son of *Muco Dovvinias*," where *Muco Dovvinias* means the clan or family group of *Dovvinis* or *Dubin* (genitive *Duibne*), the ancestress after whom Corcaguiny is called *Corco-Duibne* in Medieval Irish. We have the same formula in the rest of Ireland including Ulster, where as yet very few Ogams have been found at all. It occurs in South Wales and in Devonshire, and also on the Ogam stone found at Silchester, in Hampshire. The same kind of family group is evidenced also by an inscription at St. Ninian's, in Galloway; and, to go further back—perhaps a good deal further back—we come to the bronze discovered not long ago at Colchester, and dating from the time of the Emperor Alexander Severus, who reigned from 222 to 235. This is a votive tablet to a god Mars Medocius, by a Caledonian Pict, who gives his name as Lossio Veda, and describes himself further as *Nepos Vepogeni Caledo*. He alludes to no father, and *Nepos Vepogeni* is probably to be rendered Vepogen's sister's son. At any rate, the Irish word corresponding etymologically to the Latin *nepos* has that sense in Irish; but so far as I know it has never been found meaning a nephew in the sense of brother's son. That may serve as an instance how the ideas of another race penetrated the fabric of Goidelic society; for here we must suppose a time to have come when there was no longer any occasion for a word meaning a brother's son, which, of course, there never was in the non-Celtic society which ranked men and women according to their birth alone.

Now this Caledonian Pict was not exceptional among his kinsmen, for they succeeded in observing a good deal of silence concerning their fathers down, one may say, to the twelfth century. It is historical that the king of the northern Picts was not wont to be the son of the previous king. In short, when the Celtic elements there proved strong enough to ensure that the son of a previous king should succeed, a split usually took place, the purer Picts being led by the rule of succession by birth to set up a king of their own. The fact is not so well known that the same succession prevailed also some time or other at Tara in Ireland: it is proved by a singular piece of indirect evidence, the existence of a tragic story to explain why "no son should ever take the lordship of Tara after his father, unless some one came between them." The last clause is due, I should say, to somebody who could not understand such a prohibition based on the ancient rule that a man's heir was his sister's son. This would be, according to Irish legend, in the lifetime of Conor mac Nessa.

It is curious to notice how the stories about the Pictish *ménage* seemed to have puzzled ancient authors. I will only cite one instance, to wit, from Golding's sixteenth century translation of what then passed as the production of Solinus, and what may now pass, even according to Mommsen, as quite old enough for my present purpose. It runs thus: "From the Promontorie of *Calydon* to the Iland *Thule* is two dayes sayling. Next come the Iles called *Hebudes*, five in number, the inhabiters whereof know not what corne meaneth, but liue onely by fishe and milke. They are all vnder the gouernment of one King. For as manie of them as bee, they are seuered but with a narrowe groope one from another. The King hath nothing of hys own, but taketh of euery mans. He is bounde to equitie by certaine lawes: and least he may start from right through couetousnesse, he learneth Justice by pouertie, as who may have nothing proper or peculiar to himselfe, but is found at the charges of the Realme. Hee is not suffered to haue anie woman to himselfe, but whomsoeuer he hath minde vnto, he borroweth her for a tyme, and so others by turnes. Wherby it commeth to passe that he hath neither desire nor hope of issue."

The man who wrote in that way presumably failed to see that the king was not subject to any special hardship as compared with the other men in his kingdom, where none of them had any offspring that he could individually call his own. This, be it noticed, refers to the Hebrides, not, as sometimes happens, to the more distant island of Thule, where there was also a king, as any reader of "Faust" will tell us.

We now come to the Celts, and begin with Pliny's version of Cæsar's words about the division of Gaul into three parts, as follows: *Gallia omnis Comata uno nomine appellata in tria populorum genera dividitur, amnibus maxime distincta. A Scalde ad Sequanam Belgica, ab eo ad Garunnam Celtica eademque Lugdunensis, inde ad Pyrenaei montis excursum Aquitanica, Aremorica antea dicta.* We may for the present dismiss the third or Aquitanic Gaul from our minds; but Belgic and Celtican Gaul may be taken as representing the two sets of Celts of our own islands. The Belgic Gauls began last to come to this country, and their advent seems to fall between the visits of Pytheas and Julius Cæsar: that is, roughly speaking, between the middle of the fourth century and that of the first century B.C. In this country they came to be known collectively as Brittanni or Brittones, the linguistic ancestors of the people who have spoken Brythonic or the *Lingua Brittannica*, such as the Welsh, the Cornish, and the Strathclyde Britons. As to the others Celts, it is much harder to say when or whence exactly they came—I mean the linguistic ancestors of the Gaels of Ireland, Man, and Scotland, that is to say, the peoples whose language has been Goidelic. Some scholars are of opinion that there were no Goidelic-speaking peoples in Britain till some such came here from Ireland on sundry occasions, beginning with the second century, in the time of the Roman occupation, but how the Goidels would be supposed by them to have reached Ireland I do not exactly know. My own notion is that the bulk of them reached that country by way of Britain, and that they arrived in Britain, like the Belgic Gauls later, from the nearest parts of the Continent; for this would be previous to the appearance of the Belgic Gauls on the western sea-board of Europe: that is to say, at a time when Celtica extended not merely to the Seine, but to the Scheldt or to the Rhine, if not further. Then as to the time of the coming of the ancestors of the Goidels, it has been supposed coincident with a period of great movements among the Celts of the Continent, in particular the movements which resulted, among other things, in some of them reaching the shores of the Mediterranean and penetrating to the heart of the Iberic peninsula. Perhaps one would not be far wrong in fixing on the seventh and the sixth centuries B.C. as covering the time of the coming of the earlier Celts to our shores.

In Britain I should suppose these earlier hordes of Celts to have conquered most of the southern half of the island; and the Brythonic Celts, when they arrived, may have overrun much the same area, pushing the Goidelic Celts more and more towards the west. Under that pressure it is natural to suppose that some of the latter made their way to Ireland, but it is quite possible that their emigration thither had begun before. Some time or other previous to the Roman occupation the Brythonic people of the Ordovices seem to have penetrated to the sea between the rivers Dovey and Mawddach, displacing probably some Goidels who may have gone to the opposite coasts of Ireland; but more traces in Irish story appear of invasions on the part of the Dumnonii, who possessed the coast between Galloway and Argyle. These were so situated as to be able to assail Ireland both in front and from behind, and this is countenanced to some extent by Irish topography, not to mention the long legends extant as to great wars in the west of Ireland between the Tuatha Dé Danann and invaders including the Fir Domnann. I suspect also that it was the country of these northern Dumnonians which was originally meant by Lochlinn, a name interpreted later to mean Norway.

Such are some of the faint traces of the Goidelic invasions of Ireland from Britain, but it is possible—perhaps probable—that Ireland received settlers on its southern coast from the north-west of Gaul at a comparatively late period, at the time, let us say, when Cæsar was engaged in crushing the Veneti and the Aremoric League. This has been suggested to me by the name of the Usdiæ, which probably survives in the first syllable of *Ossory*, denoting a tract of country now, roughly speaking, covered by the county of Kilkenny, but which may have been considerably larger before the Déisi took possession of the baronies of the two Decies and other districts now constituting the county of Waterford, not to mention possible encroachments on the part of Munster on a boundary which seems to have been sometimes contested. Now the Continental name which invites comparison with that of the Usdiæ is that of the Ostiæi, who in the time of Pytheas appear to have occupied the north-western end of what afterwards came to be called Brittany; they were also called Ostiones, and more commonly Osismi. I see no reason to suppose that the ships of the Aremoric League could not make the voyage from Brittany to the principal landing-places on the south of Ireland from the Harbour of Cork to that of Waterford, and I gather from Ptolemy's Geography that Ireland was relatively better known on the Continent than Britain, although the latter had been in a manner connected with the Roman world. This I should explain somewhat as follows:—Cæsar, who knew very little about the west of Britain and probably less about Ireland, says that in his time the great druidic centre of Gaul was in the country of the Carnutes, somewhere, let us say, near the site of the present town of Chartres, that druidism had been introduced from Britain to Gaul, and that those who wished to understand it had to go to Britain to study. The authors of antiquity tell us otherwise nothing about druids in Britain except that Tacitus speaks of such in the Annals, in his well-known passage as to Suetonius Paulinus landing with his troops in Anglesey and the scene of slaughter which ensued. Indeed, one may go further and say that there is no proof that any Belgic or Brythonic people ever had druids: they belonged to the Celtican Gauls and the Goidelicising Celts of Britain and Ireland, who had probably accepted the institution from the Pictish race. At any rate it is significant that the Life of St. Columba introduces the reader to a genuine druid at the court of the Pictish king, near Inverness, where, as well as on Loch Ness, the saint had to contend with him. In any case, it is highly probable that druidism was no less a living institution in Ireland than in the Goidelic and Pictish parts of Britain. Presumably it was more so, and it may be conjectured that Gaulish students of druidism visited Ireland no less than Britain; also, *vice versâ*, that Irish druids paid visits to the Celtican part of Gaul where druidism flourished on the Continent, and in a word that there was regular intercourse between Gaul and the south of Ireland. If the druids of Ireland, who, among other *rôles*, played that of schoolmasters and teachers in that country, travelled to Celtica, they must have spread on the Continent some information about their native country, while generations of them cannot have returned to Ireland, with their druidic pupils, without bringing with them some of the arts of civilised life as understood in Gaul: among these one must rank very decidedly the art of writing, which the druids practised. Now you know the usual account given of the ordinary Latin for Ireland, namely *Hibernia*—to wit, that it was suggested by such native names as that of one of the greatest tribes of that country, namely the ’Ιούερνοι or *Iverni*, and that it had its *v* ousted when Latin began about the fourth century to write *b* for *v*, and that an *h* was then prefixed to make the word *Hibernia* properly connote the wintry climate which our sister island had always been supposed to enjoy. But now comes the question, where did Pomponius Mela, who flourished about the middle of the first century, get his *Iuverna*, which Juvenal also used? Doubtless from a druid like Dálan, or some other educated native of Ireland, for what the editors print as *Iuverna*, *Iuuerna*, or *Juverna* would appear in ancient manuscripts as *IVVERNA* or *iuuerna*, in which the first two syllables are spelt correctly with *v v* according to a system of spelling well known in Ogmic writing centuries later. But a particular system of spelling seems to me to imply writing, and thus one is encouraged to think that the Ogam alphabet may have been invented no later than the first century in the intercourse I have conjectured to have been going on between the north-west of Gaul and the south of Ireland, where the majority of Ogam inscriptions are now found. But what has archæology to say on the question of such intercourse?

After this digression I come back to the two main streams of Celtic immigration from the same parts of the Continent in two different periods of time. The later of these introduced the *Lingua Brittannica*, which was practically a dialect of old Gaulish; but the affinities of the other Celtic language of these islands, the Goidelic, are not so easy to determine. I have long thought that I can identify traces of it on the Continent, and that its principal home was in the region which Pliny called Celtica, between the Garonne and the Seine. I ventured accordingly to call it *Celtican*, as the simpler word *Celtic* had already been wedded to a wider signification. Since then the existence of that language has been placed beyond doubt by the discovery of fragments of a calendar engraved on bronze tablets. This find was made about the end of 1897 at a place called Coligny, in the department of the Ain, and the pieces are now in the muséum at Lyons. It is difficult to say for certain whether Coligny is within the territory once occupied by the Sequani, or else by the Ambarri, a people subject to the Ædui, who were rivals of the Sequani and Arverni. The name of the Sequani would seem to have belonged to the Celtican language, and Mr. Nicholson, in his interpretation of the calendar, has ventured in this instance to call it Sequanian. But two inscriptions in what appears to be the same language have come to light also at a place called Rom, in the Deux Sèvres and on the Roman road from Poitiers to Saintes. This Celtican language is to be carefully distinguished from Gaulish, but it is not exactly what I expected it to be: it is better. For several of the phonetic changes characteristic of Goidelic had not taken place in Celtican. Among other things it preserves intact the Aryan consonant *p*, which has since mostly disappeared in Goidelic, as it had even then in Gaulish. This greater conservatism of Celtican enables one to refer to it the national appellation of the people of the region in question, namely, that of the *Pictones*, from which it is impossible to sever the name of the Picts of Britain and Ireland, who are found also called *Pictones* and *Pictanei*. Here I may mention that Mr. Nicholson calls attention to instances of tattooing on some of the faces on ancient coins belonging to Poitou and other parts of western France. In the light of the names here in question one sees that *pictos* was a Celtican word of the same etymology, and approximately, doubtless, of the same meaning, as the Latin word *pictus*, that the Celticans had applied it at an early date to the Picts on account of their habit of tattooing themselves, and that the Picts had accepted it (with its derivative *Pictones*) so generally that by the time when the Norsemen arrived in the North of Scotland, it was the name which the natives gave them as that by which they called themselves. That is practically proved by the Norsemen calling Caithness and Sutherland *Petta-land* or the Land of the Picts, and the sea washing its northern shore *Pettalands fiorth*, which survives modified into Pentland Firth.

Another Celtican word of great interest here has by a mere chance come down in a high German manuscript written before the year 814; it is *Chortonicum*, and occurs among a number of geographical names, several of which refer to Gaul, so that Chortonicum may very well have meant the country of the Pictones. At all events, the great German philologist, Pott, at once saw that it was to be explained by reference to the word Cruithne, "a Pict," with which it decidedly goes as distinguished from its Brythonic equivalent *Prydyn* (or the older *Priten*), with an initial *p*. The Celtican form originally meant was some such vocable as Qurtonico-n, with the *qu* which was usual in Celtican and early Goidelic, where it formed, in fact, one of the most conspicuous distinctions between those languages and Brythonic or Gaulish, in which *qu* had been changed into *p*.

My remarks have again run into tiresome details, but it is only by attending to such small points that one can hope to force language to yield us any information in the matter of ethnology. It may perhaps help in some measure if I sum up what I have been trying to say, thus:

The first race we have found in possession of the British Isles consisted of a small, swarthy population of mound-dwellers, of an unwarlike disposition, much given to magic and wizardry, and perhaps of Lappish affinities: its attributes have been exaggerated or otherwise distorted in the evolution of the Little People of our fairy tales.

The next race consisted of a taller, blonder people, with blue eyes, who tattooed themselves and fought battles. These tattooed or Pictish people made the Mound Folk their slaves, and in the long run their language may be supposed to have been modified by habits of speech introduced by those slaves of theirs from their own idiom. The affinities of these Picts may be called Libyan, and possibly Iberian.

Next came the Celts in two great waves of immigration, the first of which may have arrived as early as the seventh century before our era, and consisted of the real ancestors of some or our Goidels of the Milesian stock, and the linguistic ancestors of all the peoples who have spoken Goidelic. That language may be defined as Celtican so modified by the idioms of the population which the earlier Celts found in possession that its syntax is no longer Aryan.

Then, about the third century B.C., came from Belgica the linguistic ancestors of the peoples who have spoken Brythonic; but, in the majority of cases connected with modern Brythonic, they are to be regarded as Goidels who adopted Brythonic speech, and in so doing brought into that language their Goidelic idioms, with the result that the syntax of insular Brythonic is no less non-Aryan than that of Goidelic, as may be readily seen by comparing the thoroughly Aryan structure of the few sentences of old Gaulish extant.

Those are the races which have been inferred in the course of these remarks, in which I have proceeded on the principle that each successive band of conquerors has its race, language and institutions eventually more or less modified by contact with the race, language and institutions of those whom it has conquered. That looks simple enough when stated so, but the result which we get proves complicate. In any case I have endeavoured in this address to substitute for the rabble of divinities and demons, of fairies and phantoms that disport themselves at large in Celtic legend, a possible series of peoples, to each of which should be ascribed its own proper attributes. But that will only be possible if we can enlist the kindly aid of the Muse of Archæology.

## *THE INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.*

THIS congress was held in Paris during the last week of July, M. Moissan being president and M. Berthelot honorary president. The work was divided into ten sections: analytical chemistry, chemical industry of inorganic products, metallurgy, mines and explosives, chemical industry of organic products, the sugar industry, chemical industry of fermentation, agricultural chemistry, hygiene, food analysis, medical and pharmaceutical chemistry, photography, and electrochemistry. More than two hundred papers were read and discussed, and numerous resolutions were passed, of which the following were the most important. In view of the great inconvenience caused commercially by uncertainty in the atomic weights used by analytical chemists, the congress, hoping that the adoption of the atomic weight of oxygen as a base ($O=16$) would lead to a greater certainty and to a simplification in the calculation of atomic weights, agreed to work in unison with the International Commission on atomic weights. It further suggested the necessity for an International Commission for fixing methods and coefficients of analysis in commercial work. Committees were also appointed to deal with questions of indicators in volumetric work, analysis of manures, potash estimation, and the use of sulphurous acid in wine. In the second section the chief questions dealt with were the determination of high temperatures, construction of glass and porcelain furnaces, the manufacture of sulphuric acid, and of barium and hydrogen peroxides. In the section of metallurgy, mines and explosives, papers were read dealing with the sampling of minerals, the constitution of iron and steel, the use of the microscope in the study of metals, utilisation of waste heat, and the estimation of sulphur, manganese and phosphorus in metals. In the section dealing with the industry of organic substances the most important discussion was on the use of alcohol for other than drinking purposes, and a series of resolutions was passed stating that in the opinion of the congress no duty should be charged upon alcohol used in the preparation of pharmaceutical and chemical products. In the case of alcohol intended for use as fuel, the substances added should be of a character appropriate to its use, not too costly, and not containing any non-volatile substance. Any attempt to recover pure alcohol from methylated spirit should be liable to severe penalties, and all makers of stills should be compelled to give particulars to the excise authorities of stills sold or repaired. In the other sections discussions were held on the relation of the sugar industry to the State, the methods of analysis of wines and spirits, the carbide industry, manufacture of percarbonates, and numerous other papers of interest.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

IT is officially announced that Mr. L. R. Wilberforce, demonstrator in physics at the Cavendish Laboratory, Cambridge, and University lecturer in physics, has been appointed to the Lyon Jones chair of experimental physics at University College, Liverpool, vacated by the removal of Dr. Oliver Lodge to the University of Birmingham.

THE Admiralty has created an important new post in the Dockyard staff, namely, that of electrical engineer, to rank next to the four chief assistant engineers. To fill this post the Admiralty has chosen Mr. Louis J. Steele, M.I.E.E., late chief engineer of Messrs. Verity, and formerly assistant engineer with Messrs. Johnson and Phillips. Mr. Steele received his training at the Technical College, Finsbury, under Prof. Silvanus Thompson and Prof. Perry, and carried off the certificate of the College in 1890. He will be attached to the Dockyard staff at Portsmouth.

INSTRUCTION in chemistry is well provided for at the Goldsmiths' Institute, New Cross. During the session about to commence, Mr. W. J. Pope will give courses of lectures on oils, fats and waxes, organic chemistry with special reference to recent work and current views, inorganic chemistry and stereochemistry. In this last course of lectures, the principles which form the foundation of stereochemistry will be discussed, together with the methods which have led to the discovery of stereoisomerism amongst compounds of carbon, nitrogen, tin and sulphur. Particular attention will be paid to the bearing of stereochemistry upon current chemical problems. Lectures in chemistry will also be given by Mr. Stanley J. Peachey.

DURING the past year the Degree of Doctor of Philosophy was conferred by twenty-two Universities in the United States upon 233 candidates. The distribution of these degrees among the various Universities, and the subjects taken, are dealt with in an article in *Science*. It appears that 120 of the degrees were granted to students of the humanities, and 113 for scientific subjects. The tables show that the humanities are favoured at Havard and Yale Universities, and the sciences at Johns Hopkins, Columbia and Cornell Universities. Last year Johns Hopkins gave more than its proportionate share of degrees in chemistry, physics, zoology and physiology, Chicago in mathematics, geology, sociology and education, Harvard in physics, zoology and anthropology, Columbia in astronomy, botany, zoology and education, Yale in palæontology and psychology, Cornell in botany and psychology, and Clark in mathematics, psychology and education. The six science subjects in which most students presented theses are as follows:—Chemistry 26, physics 15, botany 12, mathematics 11, zoology 11, psychology 9.

EVER since the funds were provided for technical education in this country, it has been insisted upon in these columns, and by men of science generally, that such education could only be profitably carried on by giving rational instruction in scientific principles instead of attempting to teach actual processes and trade methods, which are constantly in a state of flux on account of new developments. The most gratifying characteristic of educated opinion at the present time is the acceptance of this view; and it is especially noteworthy in connection with the substitution of nature study for agriculture in rural schools. In an address recently delivered before the Cheshire College of Agriculture, Prof. Robert Wallace dwelt upon the relation between the work of an agricultural school and actual farm work, and showed himself in complete sympathy with the view which has been expressed over and over again in these columns. Here is the case in a few words:—"What a young farmer should learn is not ordinary farm work, viz. to plough and harrow a given area in the day. He can become an expert at that kind of thing at home to greatest advantage, without cost for instruction, and at the same time prove a valuable aid to his father. He requires to be taught just those things which are not to be learned on an ordinary farm, to have explained to him the meaning of processes which are founded on scientific principles, and to become familiar with the common facts of those sciences which bear upon agricultural practice." If this had been borne in mind by Technical Instruction Committees in rural districts from the time they came into existence, their efforts would have received more encouragement from practical men, and have been attended with better results, than have been attained in many cases.

## *SCIENTIFIC SERIALS.*

*Transactions of the American Mathematical Society*, vol. i. No. 3.—Wave propagation over non-uniform electrical conductors, by M. I. Pupin, is a paper read before the society in December last. The main object of it is the solution of a problem which, looked at from a purely mathematical point of view, can be stated as follows:—Find the integral of the partial differential equation $L\frac{d^2y}{dt^2}+R\frac{dy}{dt}=\frac{1}{C}\frac{\delta^2y}{\delta s^2}$, and determine it so as to satisfy $k+2$ boundary conditions, where $k+1$ is the number of coils. The principal difficulty is to determine the proper mathematical formulation of these sundry conditions so as to obtain a system of equations which can be readily solved. The paper is illustrated by diagrams which put the problems discussed in a clear light.—"Ueber systeme von differentialgleichungen dessen vierfach periodische functionen genüge leisten," by M. Krause, was presented at the Chicago (April) meeting of the present year. References are given to Hermite ("Sur quelques applications de la théorie des fonctions elliptiques," 1885), and to a paper by Picard (*Comptes rendus*, Band 89), and to previous work by the author.—E. B. van Vleck follows with a paper on linear criteria for the determination of the radius of convergence of a power series. Its object is to establish criteria for the convergence of a power series when the $(n+1)$th coefficient $A_n$ is connected with the preceding coefficients by a linear relation which tends to take a limiting form as $n$ increases indefinitely. The criteria include Cauchy's ratio-test as a special case, and may be looked upon as an extension of the test, and are applicable in cases in which the simple ratio-test fails. The paper closes with two theorems which are an extension for the case of two variables, criteria for the convergence of power series in such a case are stated to be very rare.—On the existence of the Green's function for the most general simply connected plane region, by W. F. Osgood.—A short but suggestive note—"D" lines on quadrics, by A. Pell. These lines, so named by Cosserat, were originally considered by Darboux. They are the lines drawn upon a surface in such a way that the osculating sphere at every point is tangent to the surface at that point. In addition to the above, the lines have been studied by Enneper and Ribaucour (for surfaces in general). In the present paper the author applies the theory of elliptic functions to the integration of Darboux's differential equation, and obtains an idea of the appearance of the lines and also some of their properties.—Starting from an article, by Prof. F. Morley, in the previous number of the *Transactions*, F. H. Loud gives sundry metric theorems concerning $n$ lines in a plane. By giving a different interpretation to formulæ got by Prof. Morley, Mr. Loud obtains a new series of theorems and other results of some interest.—An application of group theory to hydrodynamics, by E. J. Wilczynski. It was observed by Sophus Lie that the stationary motion of a fluid can serve as a perfect picture of a one-parameter group in three variables. Apparently this fact has not been utilised for the purposes of hydrodynamics. This paper does this. Amongst other advantages, the treatment, from the new standpoint, leads to special cases of exceptional interest and importance, which otherwise appear to be difficult and unpromising.—Dr. L. E. Dickson, following up work recently published in the *Proceedings* of the London Mathematical Society (vol. xxxi. pp. 30, 351), contributes an article on the determination of an abstract simple group of order $2^7 \cdot 3^6 \cdot 5 \cdot 7$, holohedrically isomorphic with a certain orthogonal group and with a certain hyperabelian group (contributed to the Chicago [April] meeting of the society).

In the *Journal* of the Royal Microscopical Society for August, Mr. E. M. Nelson has one of his useful technical articles on the "lag" in microscopic vision, as well as a historical account of the improvements in the structure of the microscope introduced by the firm of Ross. Mr. E. B. Stringer describes a new form of fine adjustment. Miss A. Lorrain Smith gives a description of some new microscopic fungi, including a new species of Entomophthora, not parasitic, but saprophytic on dead animal tissues. There is, in addition, the usual summary of current researches relating to zoology, botany and microscopy.

In the *Journal of Botany* for August, Messrs. W. and G. S. West have a second instalment of their notes on freshwater algæ, in which some new species and varieties are described. The remaining papers are descriptive or geographical.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, September 10.—M. Maurice Lévy in the chair.—Occultation of Saturn by the moon on September 3 observed at the Observatory of Lyons, by MM. J. Guillaume, G. Le Cadet and M. Luizet.—On differential systems with a general uniform integral, by M. Paul Painlevé. Four types of systems are examined, problems in mechanics such as the movement of a heavy body fixed by a point, the inversion of total differentials, the case where the general integral of a differential system does not admit of transcendental singularities, and the study of the integrals of a differential system in a real field.—On the liquefaction of air by expansion with production of external work, by M. Georges Claude.—On the dielectric cohesion of gases and vapours, by M. E. Bouty. The experiments previously described upon the relation existing between the distance at which insulation breaks down and the pressure of the gas have been extended to vapours of liquids. Results of measurements for water, and eleven organic liquids, are given in the present paper.—On the modification of the electrical and organic properties of cables under the prolonged action of currents, by M. Georges Rheins. When a cable is submitted to the action of an alternating current it preserves its electrical and organic properties intact. With a continuous current in one direction the cable gradually loses its electrical properties, this effect being produced by the slow penetration of the copper from the wire into the sheath. The effect is similar with both gutta and paper coatings.—New researches on the absorptive power of hæmoglobin for oxygen and carbonic acid, by M. L. G. de Saint-Martin. As the result of numerous experiments quoted, the author is of opinion that, contrary to the views generally held, it is impossible, especially in pathological cases, to estimate hæmoglobin by means of the absorbing power of the blood.—On the nitrocelluloses, by M. Léo Vignon. Both the nitrocelluloses and the nitro-oxycelluloses energetically reduce Fehling's solution, their reducing power being apparently independent of the degree of nitration. The reducing powers of the nitration products of cellulose and oxycellulose are of the same order, about one-fifth that of inverted sugar.—On the wood of the Conifers of peat bogs, by M. L. Géneau de Lamarlière. In the wood of Conifers taken from a peat bog, the intercellular layer formed of lignin and pectic compounds is intact, whilst the internal portion has been strongly attacked by microbial action. The lignin and cellulose have disappeared, an amorphous substance remaining behind which is soluble in potash after the action of chlorine. The material resembles callose.—Influence of a dry or moist medium upon the structure of plants, by M. Eberhardt. Compared with normal air, the effect of dry air is to increase the thickness of the epidermal cuticle and the number of stomata, to make the cork layer form earlier, to increase the production of ligneous tissue, and to cause an increase in the amount of pallisade tissue in the leaf.

THURSDAY, SEPTEMBER 27, 1900.

## *THE MAMMALS OF SOUTH AFRICA.*

*The Fauna of South Africa; Mammals.* Vol. i. *Primates, Carnivora and Ungulata.* By W. L. Sclater. Pp. xxx + 324; illustrated. (London: Porter, 1900.)

IN our review of the "Birds of South Africa" (vol. i.), published earlier in the year, reference was made to the scope of the present series of volumes and the peculiarities of the South African fauna; and it will therefore be unnecessary to recapitulate what has been there written. In the introduction to the volume before us Mr. Sclater remarks that since 1832 no one has attempted to give a complete account of the mammals of South Africa, attention having been concentrated by writers on this subject to the larger forms which constitute the chief attraction to sportsmen and travellers. Accordingly, in the case of the smaller representatives of the class the author has practically a clear field before him, much labour being necessary to collect and collate the numerous papers which have been written of late years on the Rodents and other small mammals of Africa. This portion of his subject is, however, reserved for the second volume; and at present we have only to consider how Mr. Sclater has treated the section dealing with the larger types of mammalian life.

As he himself admits, his task in this respect has been a comparatively easy one; the "Book of Antelopes" clearing the way in regard to that very important group of the Ungulata, while the Zebras have been carefully worked out by Mr. Pocock and other naturalists, and the Carnivora have attracted the attention of numerous writers. On all these valuable sources of information Mr. Sclater has drawn largely; and it is no discredit to him if the work partakes to a very considerable degree of the nature of a compilation, and contains comparatively little that is new and original. Indeed, this is fully acknowledged in the Introduction, where the author takes care to state that in his account of the habits of the different animals he has relied on the observations of others, and endeavoured to compile from published writings and manuscript letters an adequate and readable account of each.

By these observations we by no means intend to imply that Mr. Sclater's work is in any sense a superfluous or unnecessary one; the "Book of Antelopes" and other works of that description are expensive and accessible only to the few; and, as already said, there is no modern and up-to-date work treating of South African mammals as a whole.

Both in respect to his treatment of the aforesaid life-histories and in his description of the species themselves Mr. Sclater may, indeed, be fairly congratulated on the result of his labours; the volume before us being sufficiently popular and interesting to attract the attention of the sportsman, while at the same time it contains a sufficient amount of technical detail to satisfy the needs of the working naturalist. Whether, however, in these days of cheap natural histories and zoological text-books it is necessary that every work on local faunas should contain a hackneyed recapitulation of the characteristics of the orders and other large groups of animals may be a question which many would, we think, be inclined to answer in the negative. As regards the numerous illustrations in this volume, it is much to be regretted that the majority, which were executed in the Colony, are of a very inferior description, and in no wise worthy to stand alongside those borrowed from the "Book of Antelopes" and other well-known works. Probably there is not time to alter the arrangements made for illustrating the second volume; but if there be, it is most desirable that the drawings should be made and photographed in this country.

As regards the local variations presented by species, the author is perhaps a little too conservative; and although he gives full details in regard to the numerous races of Burchell's zebra, we venture to think that more might have been said, for instance, with regard to the local phases of the Kaffir cat and some of the jackals. Among the Carnivora, it is interesting to find that the author recognises the black-footed cat (*Felis nigripes*), which has been so unaccountably overlooked by recent writers, as entitled to rank as a species. And, in another group, we think he is decidedly well advised in adopting the Colonial term "Dassie" (an abbreviation of the Boer *klip-dass* = rock-badger) as the popular name for those animals which used to be scientifically known as Hyrax, until that name was displaced by the earlier Procavia.

Generally speaking, Mr. Sclater is, indeed, well up to date as regards nomenclature, both popular and scientific. He does not, however, in all cases give credit for recent emendations in nomenclature to those to whom it is due. For instance, the reader would be led to imagine that the author was the first in modern times to replace the ordinary scientific title for the eland by *Taurotragus oryx*, whereas the change was initiated last year by Mr. Rowland Ward in his "Records of Big Game." And it cannot be urged in the author's defence that the omission is due to the fact of his quoting only references from works bearing directly on South Africa, since he departs from this rule in the case of *Cephalophus grimmi* (p. 157), as well as in other instances. A change of name for which the author appears to be really responsible occurs in the substitution of *Strepsiceros capensis* for *S. kudu*; but this directly raises the question of the advisability of adopting the alliterative *S. strepsiceros*, which some would now regard as the proper name of the kudu.

On the whole, the volume appears to be remarkably free from misprints and slips. On p. 317 the author has, however, given *Elephas planifrons* as the type of Falconer's subgenus *Euelephas*, and *E. hysudricus* as that of *Loxodon*; whereas the two specific names should be transposed. But this unfortunate slip is not all, for in making these two species the respective types of the subgenera the author has totally misrepresented Falconer. Mr. Sclater has, of course, taken them as the types because they occur first in Falconer's table. But *Euelephas* of Falconer is merely the typical subgenus of *Elephas* (*Elephas* proper it would now be called), and therefore the type of the one is the type of the other; this being, of course, the Indian elephant. Again, in the paper to which Mr. Sclater refers, Dr. Falconer, in writing of the Loxodons, says that "the existing type of this group is the African elephant, which Fred. Cuvier, in 1835, proposed to erect into a distinct genus under the name of Loxodonta." A more unfortunate error, complicated by a more unfortunate slip, could scarcely be conceived.

In one other passage where the author ventures into the domain of palæontology he has scarcely been more successful, since (p. 308) he unhesitatingly accepts the alleged Cretaceous age of presumed Hyracoid remains discovered in the Argentine. Possibly, however, his omission to mention that fossil "dassies" occur in the European Pliocene may be due to the time that the volume has taken in passing through the press, although the fact was announced at the Zoological Congress held at Cambridge in 1898.

Much general interest will attach to Mr. Sclater's account of the two large mammals which have undoubtedly become extinct in South Africa in modern times. With regard to the first of these, the author remarks that the last blaauw-bok (*Hippotragus leucophoeus*) was probably killed in 1799; and that, in addition to several pairs of horns, five complete mounted specimens are known to be preserved. The quagga (*Equus quagga*) he believes to have survived in the Orange Colony till at least 1878, although it is difficult to obtain exact information owing to the Boers confounding this species with Burchell's zebra. Of the white rhinoceros it is considered not improbable that a few may still survive in Zululand, although it is sad to learn that no less than six are reported to have been killed so lately as 1894, one of these being exhibited in the museum at Pretoria. The latest information with regard to the white-tailed gnu is that a few herds were, till recently, preserved on some farms in the Orange Colony and the Transvaal; while it is suggested that a few stragglers may survive in the Kalahari, Gordonia and German South-west Africa. Much anxiety will now be felt by naturalists as to what has happened to the gnus, and also to the blesboks, till lately preserved in the Boer Republics; and it is to be hoped that those responsible for the settlement of these districts will do all in their power to protect such remnants as the war may have left.

We hope ere long to have the pleasure of congratulating Mr. Sclater on the completion of his task. R. L.

---

## OUR BOOK SHELF.

*Acetylene, a Handbook for the Student and Manufacturer.* By Vivian B. Lewes, F.I.C., &c. Pp. xxvi + 978. (Westminster: Archibald Constable and Co., Ltd., 1900.)

IN this handsome volume of nearly 1000 pages, Prof. Lewes has presented the English reader with a handbook on the manufacture and use of acetylene which in completeness of scope and wealth of illustration will compare with its French and German rivals.

In the first part (consisting of four chapters) the scientific history of acetylene and its properties is set forth with considerable detail; useful summaries of many researches are given, and references to the original memoirs are added. The question of the discovery of "commercial calcium carbide" is discussed with discrimination, the chief credit being assigned to the Canadian engineer, Mr. T. L. Willson. The reactions of acetylene, especially with metallic salts, are fully considered.

Part ii., the most important in the book, describes the development of the electric furnace, and its special adaptation to the manufacture of calcium carbide. The generation of acetylene by the action of water on the carbide is next considered, and then the question of impurities and their removal is discussed. Most of the figures illustrating this portion of the book are clear and satisfactory, but a few are indistinct and on too small a scale. The chapter on the combustion of acetylene is illustrated by a number of useful drawings of burners and flames, and full data are given for a comparison between acetylene and other methods of illumination, both as regards prime cost and working expenses. We think Prof. Lewes has shown himself eminently fair in the discussion of this subject.

The method of treatment adopted by the author naturally leads to some repetition, but in a book of reference this will not be felt an inconvenience. It was perhaps hardly necessary to give the author's "acetylene theory of luminosity" twice over. In a new edition we hope that the number of small inaccuracies will be reduced. We did not expect to find a chief gas-examiner saying that "sulphur dioxide, in ill-ventilated apartments, will absorb oxygen and moisture from the air, and will in this way become converted into minute traces of sulphuric acid, which, concentrating themselves upon any cold surface in the room, give rise to corrosion," &c. The Harcourt pentane standard is not approved of, apparently, by Prof. Lewes, who states that it was first described in 1887. It was described ten years earlier. The specific heats of gases given on page 609 are incorrect, and several names are wrongly spelled, *e.g.* Vielle should be Vieille (p. 68), Smithell should be Smithells (563). In spite of small errors, the book is a mine of information, and will be useful, both to chemical students and to others interested in the making and use of acetylene.

*Wireless Telegraphy and Hertzian Waves.* By S. R. Bottone. Pp. 113. (London: Whittaker and Co., 1900.)

THERE are many whose interest in wireless telegraphy will take the form of a desire to experiment for themselves, and who, whether from inclination or necessity, will prefer to do so with home-made apparatus. To these the little book before us will especially commend itself.

The first half of Mr. Bottone's work is devoted to "preliminary notions," "historical considerations," and to a chapter on electric waves. This earlier half seems to us to leave much to be desired. Thus a clear elementary description of the fundamental experiments of electrical science is followed (p. 12) by a very obscure summary of the properties of electric charges and currents. Again, the confusing of the words "stress" and "strain" will not please the reader accustomed to the modern strict usage of these terms.

The description of apparatus in these earlier chapters is often involved, and many sentences will be found which through faulty punctuation or other small errors are not at once intelligible. A considerable amount of repetition also seems to occur, apart from deliberate recapitulation.

The later part of the book includes a number of really good descriptions in detail of how to make such apparatus as a small induction coil, a Wimshurst machine, a relay, or a coherer; and the author is evidently familiar with the little practical difficulties which arise. Possibly the importance of making a dimensioned drawing before starting work might have been emphasised; but in all other respects these "workshop recipes" seem very complete and well suited to the wants of those about to make such apparatus. D. K. M.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Vibrissæ on the Forepaws of Mammals.

IT is well enough known that carnivorous and other—especially nocturnal—animals are provided with numerous long hairs, generally called vibrissæ, upon various regions of the face. The "whiskers" of the cat are a familiar example. But it is not so widely known that there exists very commonly in those same creatures a tuft of long hairs upon the wrist, which are connected with a large nerve. There have been incidental references to these structures; thus Mr. Bland Sutton described and figured them in several Lemurs. But it is not, I believe, a matter of common knowledge that they are present in a great variety of mammals. I have examined members of the groups, Lemuroidea, Carnivora, Rodents, and Marsupials, and invariably found these structures in those members of the groups in question which use their forepaws as climbing or grasping organs, or in both ways. They are generally not very conspicuous, as the individual hairs are often not markedly thicker than those of the surrounding fur. But often they contrast by their colour. In a pale, almost albino, example of the squirrel *Sciurus maximus*, the hairs were especially obvious, owing to their being black, and thus contrasting with the pale brown of the surrounding part of the pelage. In a black cat the same vibrissæ were white. It is always, however, easy to assure oneself of their presence by the sense of touch. The bundle of these rather stiff hairs and the thick nerve termination cannot be missed, if the skin be gently squeezed. In a newly born phalanger this structure was particularly obvious; but in a kangaroo of corresponding age there were no signs of an elevation of the skin bearing thick hairs. It will be remembered that the mode of life of these two marsupials is very different. Although I have examined up to the present but few genera of mammals, it appears to me that this structure will be found to be pretty universal. I have of course not detected these arm vibrissæ in Ungulates.

Zoological Society's Gardens. FRANK E. BEDDARD.

### The Distance to which the Firing of Heavy Guns is Heard.

IN the number of NATURE for August 16, there is an article by Mr. Charles Davison on the distance to which the firing of heavy guns is heard. The writer of the article seems to wish to collect facts bearing upon this question. I can supply one bit of information of the kind desired.

In the summer of 1863, during the siege of Charleston, S.C., by the Federal forces, being at the time an officer in the Confederate Army, I went, under orders, from Macon, Ga., to Charleston by way of Millen, Augusta and Branchville. It was just at the time of the first heavy naval bombardment of Port Sumtra. The train stopping at a water tank a few miles (I do not now remember just how many) on the Macon side of Millen, and therefore somewhat farther than this place from Charleston, I heard distinctly, not only the general, more or less varying, roar of the bombardment, but also the low boom of individual guns. The sound was faint, but unmistakable in the stillness while the engine was taking water, but was lost as soon as the train got into motion again and its noise began. At Augusta, during the stop made there, I could catch the sound of the guns again, though it was interfered with a good deal by the confused noise of a large town. At Branchville, a hamlet of a few houses, the sound was easily recognised by any one, and was accompanied by a general *feeling* of tremor.

Millen is nearly due west from Charleston, and distant about 117 miles in a direct line. Augusta is approximately 25° north of west from Charleston, and about 122 miles distant. Branchville is about 35° north of west from Charleston, and at a distance of about sixty miles.

Mr. Davison says that he has but little information as to the distance at which the discharge of *single guns* has been heard. I may therefore add that the heaviest guns in use in the bombardment I refer to were the 15-inch smooth bore muzzle-loading guns carried by the Federal turreted "Monitors." I do not remember now what was reported to be the charge of powder used, but they were, of course, firing shotted cartridges—some solid shot, but more frequently shell. J. W. MALLET.

### The Solidification of Alloys.

IN a recent discussion on alloys, which took place at the Bradford Meeting of the British Association in the Section of Chemistry, a curious uncertainty was alluded to, which occurs in the cooling of certain alloys from the liquid state, as to the relative proportions of different varieties of crystals which form, depending on the rate that the cooling is proceeding with.

I would wish to draw the attention of those more particularly interested in the matter to a direction in which to look for what may be one of the causes of this peculiarity, namely, to the effect that different conductivities for heat in the different kinds of crystals may exercise in determining the relative proportions in which they form, where, as in this case, two or more varieties are possible. Where there is a difference in the conductivity of two possible varieties, the more of the better conducting material that is formed the faster in general the cooling can proceed.

The matter might be looked upon as a kind of inorganic evolution. Suppose that in the first instance round the boundaries, through which heat is passing out, of the cooling material, the two varieties form with equal facility, where the better conducting material forms heat escapes fastest and solidification of the molten material proceeds fastest, we may suppose this to follow in composition the lines of the crystals in proximity, namely, of the better conducting kind. Thus, by a kind of survival of the fittest, one of the varieties prevails.

When the cooling is very slow, where in the limit the temperature is at any moment the same throughout, this controlling influence is a vanishing quantity.

A similar principle is probably the cause of the radiating structure seen often in a cooled mass of certain materials, such as bismuth and possibly ice, which have different conductivities in different directions in the crystal. FRED. T. TROUTON.

Physical Laboratory, Trinity College, Dublin.

### The Reform of Mathematical Teaching.

As I am in full sympathy with Prof. Perry's views, my own training, somewhat on the lines suggested by him, may be of interest. I was once taught Euclid and thoroughly hated the subject. At thirteen I was sent to school in Germany, where I was taught geometry; it had so little resemblance to Euclid that I looked on it as a new subject and was delighted with it. After eighteen months I returned to England to serve my apprenticeship, but not before I had advanced as far as solid geometry, quadratic equations and trigonometry, and I believe that this early and rapid mathematical training was of inestimable advantage to me in the works. It seems unconsciously to have led me to look on practical subjects with so much of a mathematical feeling that even now my fellow engineers consider me very mathematical, yet all the subsequent mathematical training at college (Germany) only extended over another eighteen months, and I admit that I would have liked to have had more.

I now come in contact with many engineers, both old and young, and almost invariably find that they are unmathematical, *i.e.*, they cannot look at an engineering problem with an analytical eye; and no wonder, if they have been brought up on Euclid. To me these volumes seem to be a collection of mathematical puzzles, which the ancient Greeks sent each other for solution, and which are most excellently edited by Euclid. A similar collection might nowadays be made of the trying problems in the chess columns of our daily literature, and these might be so pieced together as to afford most excellent mental training, but such a work would never teach good chess playing. It would be an excellent reference book for past masters, and that is what Euclid would still be if higher mathematics had not been invented. C. E. STROMEYER.

Lancefield, West Didsbury.

### Leaf Decay and Autumn Tints.

"OBSERVATION shows," says Emile Mer, "that in most cases where wood dies in contact with living wood there is produced from the second towards the first a migration of starch and tannin, and (in a conifer) of resin; there is thus produced from the portions remaining living towards the dying or dead portions a drainage of substances, &c." These remarks refer to the formation of secondary periderm and of the duramen, but their scope and tenour may perhaps, I think, be extended to the case of forest leaves approaching the end of their existence as living organs. How does it come to pass that in autumn the leaves of some of our forest trees exhibit a brilliant livery of crimson, while others exhibit only a yellow or golden glory? Take, for instance, the case of the ash constituents in the dry substance of the leaf. It is known by analysis that the percentage of ash increases through nearly the whole life of the leaf in beech, sycamore, elm, but not in oak, larch, cherry, &c.; it depends a good deal on whether some one ash constituent (generally lime or silica) is being steadily stored up. For example, the dry leaf of *Acer campestre* on May 1 has 6 per cent. ash, and in October 16·2 per cent. ash; the dry leaf of *Prunus avium* has on April 28, 7·8 per cent., and on October 2, 7·2 per cent. ash. Now the leaf of the former tree is only yellow in autumn and never red, while that of the latter is very often beautifully crimson. In the former case there is a kind of gradual decay or death of some of the cells (mostly of the upper epidermis) which occasions a drainage of mineral and organic substances to these parts from the still living tissues. This drainage and accumulation attest, in fact, such a decay; and what is more, they seem to have a distinct influence over the ultimate autumnal coloration of the leaf itself. It is easy to understand, in fact, that the leaves which exhibit such a decay and approach to dissolution are just these wherein the chromogen precursive of the brilliant red coloration would likewise suffer an analogous kind of change, *i.e.* it would tend to become brown, to produce phlobaphene, just as it does in the outer bark which is the practically dead portion of the rind. Where this accumulation of mineral matter and all which it implies does not take place, as in cherries, currants, American oaks, pears, wild vine, barberry, &c., then the chromogen does not deteriorate; it evolves its proper pigment, and assumes the flush and glow of active living colour. On the other hand, in elms, chestnut, linden, birch, poplars, &c., which are never red but only yellow, it is only the vivid carotin attached to the last faded and now exhausted chlorophyll which gleams forth, but only for a time, and if not too much obstructed by the dull browns of decomposed carbohydrates and superoxidised tannic chromogens.

Patterdale, Westmorland.

### Homochronous Heredity and Changes of Pronunciation.

SEEING that in ancient German, or rather Gothic, Swedish, Danish, probably in French, and possibly in Sardinian, the *th* sound surviving in English (though much less frequent than it used to be) was once largely used, but nowadays Frenchmen and Germans find a difficulty with it, I should like to know whether systematic experiments have been made as to whether children of various ages of these two nationalities can pronounce it more exactly and spontaneously than their compatriots of a maturer age? I should like to make the same inquiry concerning English children and their pronunciation of the gutturals discarded or altered in such words as *night*, *bough* or *laugh?*

### The Daylight Meteor of Sunday, September 2.

As Mr. Denning expresses a wish in your issue of September 13 for further information concerning this meteor, I write to inform you of what I saw myself.

I observed the time at which the meteor fell, and made it 6.50, but my watch is no chronometer. I saw the meteor from the road, between Deganwy and Llandudno, and it appeared to fall over the Little Orme's head. If you join this point to Leyburn in Yorkshire, you have the line as near as I can give it, and I do not think it is very far out. I did not note any column of smoke or cloud after the meteor fell. Its path was vertical. Some one says its angle of appearance was 35°, and disappearance 25°, which I should say is about correct. The sun was shining brightly, though low down in the west. The brilliance was greatest just before disappearance. I have never before seen any meteor to compare with it in brightness.

38 Hillfield Road, Hampstead. T. ROOKE.

THE meteor of September 2, described in your issue of September 13, was seen in Ireland also, in even brighter daylight.

I noted the time, 6.27 p.m. (Irish), and the direction, E.N.E., from a point near Enniskerry, co. Wicklow. There was a possible error of a couple of minutes in my watch, and a considerable error possible in the estimated direction, which was a rough approximation made without a compass.

B. ST. G. LEFROY.

## THE THEORY OF IONS.

EVER since Faraday enunciated the law of electrolysis, that the same quantity of electricity passed when chemically equivalent masses of different substances were produced, it has been a matter of speculation whether this may not be due to atomic charges of electricity. Every one, in describing electrolysis and explaining how the substances evolved appeared at the electrodes without any apparent action in between them, based his description and explanation upon the supposition of electric charges on the atoms. Some substances, such as hydrogen, were given positive, and some, such as chlorine, were given negative charges, and the electric current through the liquid was explained as due to the convection of these charges by the moving atoms or groups of atoms, and the movements of these were ascribed to the electric force acting on these charges. The amount of the charge on each atom or group of atoms was proportional to its valency, and as this has with good reason always been taken as a whole number, the charges ascribed to the moving elements were all simple multiples of the charge ascribed to a monovalent atom, such as hydrogen or chlorine. All this has naturally led to the hypothesis that electricity itself is atomic. In electrolysis, at least, there is a certain minimum quantity that corresponds to a single atomic bond, and quantities of electricity transferred by electrolysis are always multiples of this unit. It was surely natural, then, to give a name to this important physical unit quantity of electricity, and it has consequently been called an "electron."

Further, in electrolysis, the electrons always appear connected with, and travelling with, certain atoms or groups of atoms. For example, in copper sulphate solutions, the positive electrons travel in pairs with the divalent copper atoms, and the negative electrons with the divalent atomic group $SO_4$. These charged atoms, or groups of atoms, playing such an important part in electrolysis, have been called "ions."

Now there is a very important difference between different liquids in their behaviour when we try to pass an electric current through them. Some are quite easily decomposed, others offer a very great resistance, and it has been a matter of most interesting speculation as to the cause of this. In the first place, most of the easily decomposed liquids are solutions in water, of acids, alkalis or salts, and this has naturally attracted attention. In the second place, these solutions are all ones in which double decompositions, and such-like chemical actions take place with facility. Can a common explanation be given of this remarkable coincidence of electric conductivity and chemical activity? Electric conductivity is due to two causes—first, the electric charges on the ions; and second, the independent mobility of these oppositely charged ions under electric force. Without entering upon the very interesting questions involved in innumerable speculations as to the causes of these charges and of the mobility of the ions, all modern theories acknowledge that, in some way or another, water, and some other liquids in a less degree, have the very remarkable property of conferring upon certain substances dissolved in them the wonderful independent mobility of the ions which we see in electrolysis.

In consequence of this mobility of these differently electrified ions, it is easy to understand their chemical activity in these conducting solutions, and thus these two important properties of these solutions receive a common explanation. No really satisfactory explanation of how the solvent water confers on substances dissolved in it this wonderful independent mobility of the ions has yet been proposed. Some writers have described the phenomena as if all that was needed was to assert that the ions move about independently, that the material, $CuSO_4$ for example, is simply dissociated into Cu and $SO_4$, and that these ions gad about freely and independently in the liquid. Such writers consequently speak of the substance as being dissociated in solution. In what is recognised as ordinary chemical dissociation there is no different electrification of the constituents into which the substance is dissociated, and there is thus an essential distinction between the independent mobility of electrified ions in solution and what is recognised as chemical dissociation. Whatever be the true account of the matter, it is almost certainly very much more complicated than ordinary chemical dissociation, and the action of the water is evidently of the first importance. There is great difficulty in explaining this independent mobility, on account of two things which have not been satisfactorily explained as yet. In the first place, it is very hard to understand why these oppositely electrified ions do not combine together in pairs as they would do if they were merely under the action of the electric forces due to their opposite electrification. In the second place, it is very hard to understand where the energy comes from that is required to separate these independent ions and keep them free from one another. When copper sulphate is dissolved in water there is very little change of temperature; if it be the anhydrous salt, there is a rise of temperature; while we would naturally expect an enormous absorption of heat to account for all the energy that would be required to separate the Cu and $SO_4$ from one another. This all shows how very different this phenomenon is from ordinary dissociation, and in consequence this peculiar action of water, and in a less degree of some other solvents, has been called "ionisation." The two most important properties of an ionised fluid are conductivity for electricity, and a remarkably chemical activity which has been shown to be directly proportional to the conductivity.

Besides liquids there are gaseous conductors of electricity. Gases do not usually conduct electricity at all. Even under circumstances when one would naturally expect them to carry electric charges on their molecules, they seem quite incapable of doing so. When the surface of a liquid is electrified and it evaporates, one would naturally expect the escaping molecules of gas to carry away with them some of the electric charge from the surface of the liquid. It is not known whether an electrified metal volatilising would or would not carry away with it some of the superficial electric charge, but ordinary liquids volatilising certainly do so to a very small extent, if at all. This may be, of course, because the charge is carried by superficial *ions*, and it is not the ions that escape, but the *molecules* of the liquid itself. But why these extremely movable ions cannot escape as a gas from the surface of the liquid is a matter still requiring explanation.

Under a great variety of circumstances, however, gases are able to conduct electricity. Leaving aside the spark, glow and arc discharges in gases at high pressures, and the well-known discharges in gases at low pressures, in all which cases there is evidently something like a breaking up of the gas itself under intense electric force, there are a number of cases in which a gas can conduct electricity under quite feeble electric forces. Within any space at all close to a spark discharge of any kind, in flames and in the gases escaping from them, in the neighbourhood of surfaces of solids illuminated by ultra-violet light, in the neighbourhood of surfaces of solids being acted on chemically by the gas, in a gas traversed by kathode rays, and in a gas traversed by X-radiations and by those various, most curious and remarkable radiations that have been classed under the name of Becquerel rays—in all these cases gases conduct electricity, apparently quite freely.

Under these circumstances it has been usual to describe a gas in this condition as "ionised," and to seek for a separate and independent mobility of its ions. Great success has attended these investigations. The difficulties that surround ionisation in liquids are mostly absent here. The ions, if left for a time to themselves, do combine together in pairs, and it requires a continuous and considerable expenditure of energy to keep them apart. The diffusion of the independent electricities has been studied, and many quantitative results that were to be expected from the theory have been proved to exist.

There is, however, an important difference between the conductivity of a gas and of a liquid. In the case of a liquid, the electricity always travels along with matter in the form of an atom or a group of atoms; in a gas there is every reason to believe that we are often dealing with electric charges which, if connected with matter at all, are connected with masses which are about 500 times smaller than a hydrogen atom. So far no good reason has been given for believing that the electric charges that move about among the molecules of a gas carry any matter along with them. There does not seem any difficulty in supposing that the electric charge of an atom can exist independently of the atom. All theories of electrolysis have supposed that electric charges are transferred within the liquid along with material atoms, but from the liquid to the electrodes all theories have supposed that the electric charges jump from the liquid atom to the electrode; and if it can jump from one atom to another, there seems no reasonable objection to believing in its independent existence. On account of the difference between the nature of the conductivity of a gas and of a liquid, it would be well to confine the term ionisation to the case of conductivity due to the mobility of charged atoms or groups of atoms, and to call the conductivity due to the existence of these mobile electric charges which are not connected with atoms by another name, such as "electronisation."

One of the most remarkable results of the study of these mobile electric charges which are unconnected with atoms is that only negative electric charges have as yet been discovered to be free from atoms; the corresponding positive charges seem to be always attached to atoms or groups of atoms. This has naturally led to a rehabilitation of the old single fluid theory of electricity in which matter plays the part of the positive fluid in the old double fluid theories, and the phenomena of electronisation, so far known, certainly lend support to this hypothesis. But we really know so little about the subject, that it is rather too soon to form anything beyond a rough working hypothesis. So long as we know that there exist outstanding, second order effects like gravitation, we are premature in concluding that the connection between positive electrification and matter proves any first order difference between positive and negative electricity, as it may be a second order effect.

The conductivity of gases produced by the pressure of these movable electric charges is in some respects more analogous to that of metals than to that of liquids. In liquids an electric current is accompanied by streams of matter, while in the electronised gas, so far as it has been observed, there may be no stream of matter attached to the electric charges which carry the current. It has consequently been suggested, and with good reason, that in solids and melted metals, which conduct metallically, the electrons are freely movable, and that this is the cause of their conductivity. There is some reason to believe that in this case also it is the negative electron which is most freely movable. Some most interesting calculations have been made upon this hypothesis, in which it has been supposed that there was something like a gaseous pressure of these mobile electrons in the metal. Thermo-electric effects have been attributed to the dependence of this pressure upon temperature, and the convection of heat accompanying electric currents has been attributed to the convection of energy of irregular motion by these electrons. The Hall effect has also been shown to be a possible consequence of a different mobility of the positive and negative electrons.

Upon these principles it is natural to attribute the magnetic properties of iron and other substances to electrons describing orbits round the atoms. These revolving electrons, in this case, represent the amperean atomic currents to which magnetisation has long been attributed. A remarkable confirmation of this has been derived from the Zeeman effect, which can be explained by the supposition that negative electrons are describing orbits round the atoms. Further, the mass that moves with these electrons has been shown to be of the same order of magnitude as the 500th part of the mass of an atom of hydrogen, which, from experiments on gaseous electronisation, seems to accompany the free electrons in a gas when it conducts.

There seems to be some reason to think that in a highly magnetisable material, such as iron, either there are more than the four electrons corresponding to its atomicity in rotation, or else that these are rotating very much more rapidly than corresponds to the vibrations of ordinary light. Some objection may be taken to the latter hypothesis from the difficulty of explaining why enormously rapid ether waves are not thereby generated in the surrounding medium, and the energy of the motion thereby lost by radiation. There are suggested explanations of this difficulty, but the other hypothesis, that matter has in it many more electrons than correspond to its atomicity, and that these latter are merely peculiar in being removable, agrees with a very interesting suggestion that all matter is built up of electrons. That an atom of hydrogen, for example, consists of some 500 electrons, one of oxygen of some 8000, and so forth. This is a natural deduction from these speculations, and receives some confirmation from its being consistent with the change in dimensions of a body as it moves in different directions through the ether which has been assumed in order to explain the experiment on the motion of the earth through the ether, which Michelson and Morley conducted. A supposition such as this naturally suggests that atoms could be built up of electrons as well as the electrons separated from matter; and if that be so, there seems no impossibility in the dreams of the alchemist, and an element of one kind may some day be transmitted into that of another. What is as yet known is, however, a very slender foundation for these speculations, and it is quite likely that matter and electricity are distinct in kind, and cannot be transmuted into one another in the way suggested.

Enough has been said in this very sketchy description of ionic theory to show how far-reaching it is; how it touches upon the confines of our knowledge and upon the borderland between physics and chemistry. Advances in our knowledge of ionic theory are likely to dispel many of the clouds surrounding the connection of matter and ether, and may lay the foundations for an intelligible structure of the physical universe. ## *THE RECENT CRETAN DISCOVERIES AND THEIR BEARING ON THE EARLY CULTURE AND ETHNOGRAPHY OF THE EAST MEDITERRANEAN BASIN.*

WHILE recently excavating the prehistoric Palace of Knossos, which lies in the great central gap between the higher ranges of Crete, mid-way between the peaks of Ida and Dicta, I was much struck by the almost continuous dualistic style of the elements. But in this case the "eternal struggle" was not between East and West. It was North and South that here fought it out. The boreal blasts which have collected from the steppes of Eastern Europe sweep almost unopposed across the Ægean, and find their first obstacle in the long mountain wall of Crete. They pour through the central gap. Not unopposed, however; they are beaten back, and their place triumphantly taken for weeks at a time, by the parching South wind—the *Notios* of the Cretan natives—which is really the *Khamsîn* of the Libyan Desert. Owing to the fact that the shoot and dumping-ground of the excavations was, perforce, at the southern end, the works were interrupted for days at a time by an overwhelming dust-cloud due to this cause, for the *Khamsîn* seems to have an affinity for dust out of proportion to its actual strength. Disagreeable, however, as were these hindrances to the work of the spade, one had at least leisure to reflect on the historic lessons supplied by these natural phenomena. Crete certainly stands geographically in closer relation to Asia Minor than it does to Africa. Carpathos and Rhodes, not to speak of minor islands, afford natural stepping-stones of intercourse. The actual relations between Crete and Anatolia, ethnic and other, must not be underrated. Yet in a broad historic point of view Crete stands apart from it. It was not like Cyprus, which, although at different times it has become an outpost of Egypt and of Europe, has always remained essentially a part of Western Asia. But the main currents of Cretan history, like those of its two prevalent winds, have been Northern and Southern—European and African. Of its two direct geographical connections, that with Greece and that with Anatolia, it has consistently held to the former. On the other hand, its intercourse with the opposite Libyan coast—the Cyrenaica—and with Egypt has been singularly continuous from a very remote period. And in this lies the high importance of the part played by the island in the early history of European culture. Germs received here from the Nile Valley and its borderlands, at a time when the greater part of Europe was still in its Stone Age, were propagated northwards and westwards, and seedlings hence derived spread in prehistoric times, and by more than one channel, as far as the British islands.

During five successive campaigns of preliminary exploration in Crete, I was able to collect a variety of evidence establishing the very early derivation of certain indigenous forms of stone vases and decorative motives from those of Egypt. A series of archaic Cretan seals exhibited designs copied almost directly from those of Twelfth Dynasty scarabs, and approximately dating, therefore, from the middle of the third millennium before our era, while steatite vases were found almost indistinguishable in form from Old Empire types of considerably earlier date. The primitive three-sided seal-stones, on which appear the first rudiments of Cretan script, reproduce the type of a three-sided seal, apparently of Libyan origin, which, from its analogy with a special class of Egyptian cylinders, approximately date from the middle of the fourth millennium B.C. So long, however, as the early archæological strata of the Cyrenaica are left as at present wholly unexplored, a great blank is still left in the materials for comparison on the Libyan side. It remains to be seen whether the Danish expedition now organising will be able to overcome the hitherto insuperable obstacles to the thorough scientific exploration of that region, but the fanatical spirit of the Senoussi is of ill omen.

What the results of these Cretan observations have certainly ascertained is that whether directly from the Nile Valley, or indirectly through Libyan intermediaries, Egyptian elements were making their way into Crete at a period which must carry back by over a thousand years the materials for approximate chronology in the Ægean world. The derivation, on steatite seals and vases of Egyptian forms, of the Twelfth Dynasty spiral ornament (only at the beginning of the Mycenæan period taken over upon metal work) is of extraordinary importance as supplying the "missing link" in the origin and diffusion of the spiral system in the early European Metal Ages. By the Danube Valley and the course of the Elbe, the old route of the amber traffic brought this spiraliform system to the Bronze Age population of North Germany and Scandinavia, and was by them in turn diffused, as has been shown by Mr. Coffey, to Ireland, whose wealth in gold made it the Rand of prehistoric Europe. On the other side, survivals of the Mycenæan adaptations of the primitive spiral ornament, which had lingered on among the Illyrian tribes of the North-West corner of the Balkan peninsula, gained a new vitality in contact with the artistic genius of the invading Celtic tribes. Assimilated by these, and transported on the wave of Belgic conquest to the North-West, the spiraliform system of design re-entered the British Isles in another form; and in Ireland, where the elder spiral branch of the Bronze Age had long since expired—lived on to supply designs to St. Columba and his missionary fellow-workers. The chains are long ones that connect the carvings of New Grange on the one side and the illuminations of the Book of Durrow on the other with the art of Twelfth Dynasty Egypt; but they run through prehistoric Crete.

Of the intercourse between Crete and the Egypt of the Middle Kingdom the Palace of Knossos has supplied a new and striking piece of evidence in a diorite figure with hieroglyphic inscriptions, which give the character of the names it bears; its good style and material have been recognised by Egyptologists as a Twelfth, or at most, early Thirteenth Dynasty work. In other words, the latest date to which it can safely be referred hardly comes down to 2000 B.C. We have here therefore a valuable indication for the approximate chronology of the earlier elements of the Palace of Knossos itself, which in any case go back beyond the period to which the remains of Mycenæ have given a name. The high level of civilisation, however, already attained in the City and House of Minos at this remote date is shown, not only by such an artistic importation from the land of the Pharaohs as the diorite figure, but by fragments of wall-painting in an already fully developed style—one represents a boy placing crocus-like flowers in an ornamental vase—and by ceramic fabrics of great beauty. In order not to confuse the evidence, I endeavoured in this year's excavations within the Palace walls, as far as possible, to confine myself to the upper and purely Mycenæan layer, and the relics found of this earlier period have therefore been comparatively limited in number. But beneath the floors of houses immediately below the Palace and on the opposite hill, Mr. D. G. Hogarth, the Director of the British School at Athens, found a whole series of vases of this early painted class, many of them showing naturalistic designs of lilies, tulips, and other flowers, presenting shapes in some cases so graceful as never to have been surpassed in any later age of Greece. This style of Cretan pottery, which has received the name of Kamáræs from the grotto where its first occurrence was described by Mr. J. L. Myres, has been found by Mr. Petrie at Kahun in Egypt, again in a Twelfth Dynasty connection. The intercourse between Crete and the Nile Valley in the third millennium before our era has thus left its traces on both shores of the Libyan sea. The approximate date thus ascertained for the earlier part of the Palace at Knossos gives additional interest to the fact that this in turn overlays a vast Neolithic settlement, for which it supplies a chronological *terminus à quo*. In the Central Court a trial shaft was excavated, which went down 24 feet through continuous Stone Age deposits containing incised, chalk-inlaid pottery, axes and mace-heads of serpentine and other materials, obsidian knives and cores, and primitive images of clay and marble akin to those from the earliest settlement of Troy.

But the great bulk of the remains of the Palace of Knossos as yet brought to light belong to the most flourishing days of the better-known Mycenæan civilisation, and are contemporary with the Eighteenth and Nineteenth Dynasties of Egypt. The building itself is of vast extent—about two acres have already been uncovered, and beside it the Palaces of Mycenæ itself, of Tiryns, and of all other such buildings on the mainland of Greece shrink into comparative insignificance. We have not here the same mighty bastions, though the megalithic gypsum blocks of the lower part of the walls are sufficiently imposing. What we see here is the island capital of a great maritime power, the memory of which survives in that of the traditional "thalassocracy" of Minos, and which seems to have rather relied on its "wooden walls." Here are vast paved courts, propylæa, spacious corridors, and successions of magazines, and, amidst a maze of lesser passages and rooms, the actual council chamber of the prehistoric kings, with its curiously carved gypsum throne in the centre. There can be little doubt that this building was the prehistoric original of the fabled "Labyrinth," the etymological meaning of which is the house of the *labrys* or double-axe, the emblem of the Cretan Zeus. This symbol is carved on the principal blocks and corner-stones, and repeated on every side of every slab of what appear to be the sacred columns of two inner shrines. The legendary fame of Dædalus, to whom both the building itself and the works of art it contained were traditionally ascribed, is fully borne out by the actual remains. Both in painting and sculpture we see here a higher level than was reached either at Mycenæ or Tiryns. For monuments of Mycenæan painting, indeed, the Palace of Knossos stands almost alone. On many of the walls the frescoes were still found adhering, almost as brilliant as when they were executed, and we have here a new revelation of ancient painting. Quite new in ancient art were certain miniature groups of ladies in fashionably dressed though somewhat *décolleté* attire, seated in animated conversation apparently in the courts and balconies of the Palace itself. In the decorative designs and the fabulous animals, such as the griffins and sphinxes, the influence of Eighteenth Dynasty Egyptian models is evident; but these foreign elements are adapted in an independent manner. Of more special interest are life-size processions of youths bearing various vases, who display a singular general resemblance to the procession of the tribute-bearing Keft chieftains on the tomb of Rekhmara at Thebes, which dates from the first half of the fifteenth century B.C. It is known that the Kefts of the Egyptian monuments represent the Mycenæan race of the Ægean isles and coast-lands. On the Knossian wall-painting, we see them in their home.

The upper part of one of these Knossian figures, which is well preserved, is of the highest ethnographic interest, as presenting for the first time a careful naturalistic pourtrayal of a Mycenæan man. The profile is of a pure European character, almost classically Greek in its regularity. The lips are somewhat full; the eyes and hair are dark—the latter somewhat curly. The head is of the high brachycephalic type. The skin shows the reddish-brown hue of Egyptian convention, just as the women are in the Egyptian manner painted white. The type of head delineated is essentially that of the race which, through all the changes of Cretan history, still remains predominant in the island. The finely-cut profile, the dark hair, the high brachycephalic skull, are as characteristic now as they were over three thousand years ago when the painting was executed. It is interesting to note that the physiognomy is distinct from the more hawk-like Armenoid type which, as Von Luschan has shown, represents the underlying ethnic element of a large part of Anatolia. It is equally non-Semitic. That this Cretan type represents that of the pre-Hellenic occupants of mainland Greece is highly probable. It still survives intact in the Illyric part of the peninsula, and I have myself been again and again struck in Cretan mountain villages with resemblances to the highland population of Albania. The Slav-speaking Montenegrins, like the Herzegovinians, so far as race and physique go, largely represent the same Illyrian element; and it was curious to notice among the Montenegrin gensdarmes recently established by the Powers in Crete the striking points of similarity to the natives of the island. Here and there, in Crete and elsewhere, varieties of the predominant "Mycenæan" type take a more aquiline cast, and show points of transition to the Armenoid race of Anatolia. The cranial type is essentially the same, and on the whole the finely-cut European physiognomy, of which this Mycenæan fresco supplies the first authentic record, may be regarded as a Western differentiation of the more Eastern form.

This ethnographic result curiously corresponds with the earliest philological evidence at our disposal. A whole series of local names in Crete, Greece proper and the Macedonian and Thoracian lands to the North, represent allied but differentiated versions of names common to Caria and a large tract of Asia Minor. Thus, to take a conspicuous instance, the Western area supplies a variety of names in *-nth*, like Korinthos, Erymanthos, Perinthos, Labyrinthos, answering to others on the Anatolian side having the *-nd-* sound, such as Kalandos, Oromandos, Pyrindos, and Labrandos. In this, as in its physical type and in other respects, Crete, it will be seen, cleaves to the Greek and Thraco-Illyrian world.

My own previous researches had been a good deal occupied with a class of early Cretan seal-stones containing signs both linear and pictographic in which I ventured to detect the rudiments of a pre-Phœnician form of writing. In regard to this matter the excavation of the Palace at Knossos produced a real revelation. In chamber after chamber whole deposits came to light of inscribed clay tablets undoubtedly representing the Royal archives. The character of the writing was of two altogether distinct classes—one hieroglyphic and one linear. The hieroglyphic script answered to that of the groups of characters that I had already noticed on a series of seal-stones of Mycenæan fabric chiefly found in Eastern Crete. The ruder prototypes of these with simple pictographic designs go back on Cretan soil to a much more remote period, and find, as already noticed, very early analogies on the other side of the Libyan sea. There can be no doubt that this script in its conventionalised form is the property of the old indigenous race of the island, the Eteocretes of the Odyssey. The linear writing, on the other hand, which forms the bulk of these Knossian archives, is of a very much more developed form. It is upright, of great elegance and curiously European in aspect, a certain proportion of the signs—some seventy of which were in common use—showing correspondences with the syllabic characters of Cyprus and also with the later Greek.

The pictorial illustrations which not infrequently accompany the linear inscriptions enable us in many cases to learn the purport of these clay documents. They thus are often seen to refer to the Royal stores and arsenals, and show a decimal system of numbers akin to the Egyptian. Others, no doubt, are deeds and correspondence like the contemporary cuneiform tablets of Babylonia. Those relating to the Royal treasure show ingots, vases and ox-heads of precious metal identical with those borne by the Keft tributaries on the wall-paintings of Rekhmara's tomb belonging to the early part of the fifteenth century B.C., a valuable indication as to date. The Palace of Knossos contains no element as late as the latest prehistoric period represented at Mycenæ itself, and the date of its destruction can hardly be brought down later than, at most, the twelfth century B.C. The most recent of the clay documents contained within it lie at least behind that date.

The result of these discoveries is therefore to carry back the existence of written documents on Greek soil some eight centuries beyond the earliest known monuments of Greek writing, and five even beyond the earliest dated Phœnician record, as seen on the Moabite stone. The whole question of the origin of writing is thus placed on a new basis. The hieroglyphic Cretan forms supply, in fact, exact correspondence with what in virtue of their names we must suppose to have been pictorial originals of the Phœnician letters. *Aleph*, the ox's head; *Beth*, the house; *Daleth*, the door; *He*, the window; *Vaa*, the peg—and indeed over two-thirds of the Phœnician series find obvious prototypes among the Cretan forms. The ingenious theory of De Rougé, which has so long held the field, and by which the Phœnician letters were derived by a selected process from early hieratic Egyptian forms signifying quite different objects, becomes henceforth untenable. The analogy supplied by the Cretan hieroglyphs in favour of a simple and natural derivation is at all events overwhelming.

It does not necessarily follow that the Phœnician letters were directly derived from the Cretan; some signs, like that of the camel's head, certainly point to the accretion of Syrian elements. But the correspondences are still so great as to point at any rate to some kind of collateral relationship. Elsewhere I have ventured to suggest that these points of community may be due to the great Ægean settlement on the coast of Canaan, of which the Philistines stand forth as the representatives, and which has left its abiding record in the name of Palestine. The Biblical traditions, as is known, give the name of "Cherethim," or Cretans to a branch of the Philistine race; and Caphtor, the isles or coastlands from which the Philistines traditionally came, has been plausibly identified with Keftô, the Ægean maritime realm of the Kefts, who on Egyptian monuments appear as the representatives of the Mycenæan civilisation. Of this special connection with Crete, the finds at Knossos already referred to afford convincing evidence. Other recent discoveries afford a singular support to these conclusions. It has been pointed out by Dr. Wilhelm Max Müller that in an Egyptian list of Keft names, going back to the Eighteenth Dynasty, appears the most characteristic of all Philistine name-forms, Achish; and it thus appears that the name was known in prehistoric Knossos earlier than in Gath. Not less significant in its way is the discovery made during the recent excavations of the Palestine Exploration Fund on, or near, the site of Gath, of imported Mycenæan pottery in the pre-Israelite stratum. More and more it appears that the high early Ægean civilisation, of which Crete is now seen to be the centre, was exercising a far-reaching influence on the coasts of Canaan before the rise of the Phœnician commercial power. Cadmus had sat at the feet of Minos, and the priceless gift which in darker days of her history he bore to Hellas, was in some respects at least a restitution of what Greece herself had given long before.

Gaza, the chief Philistine emporium—the crossing point of the caravan routes between Egypt, Syria and Southern Arabia—owed its traditional foundation to Minos, and continued down to Roman times to worship the Cretan Zeus. The great cave on Mount Dicta, which was the legendary scene of the infancy of this indigenous divinity, to whom, as we have seen, the Palace of Knossos was also consecrated, has now been thoroughly explored by Mr. Hogarth, and has produced a vast mass of votive relics illustrating the prehistoric culture of Crete from the earliest Metal Age onwards. The crevices of the stalactite columns of the lower part of the cave were found to have been utilised for the insertion of bronze offerings, especially miniature figures of the double axe, which was the particular symbol of this God. Many stone libation tables were also found representing the adaptation of early Egyptian forms, and among the votive bronzes an Egyptian figure of the god Amon Ra, whose personality presents some points of affinity to the chief Cretan God. Another bronze from this site, a miniature chariot, drawn by an ox and a ram, has a special interest as an early example of a series of votive bronzes on wheels, in the shape of cars and tripods, supporting bowls, birds and other objects, which form a feature in the remains of a wide European zone during the Late Bronze and Early Iron Age. That their ultimate source was Egypt appears probable from the four-wheeled car with the silver boat of Queen Aah-hotep; but here again we see among Cretan remains what is probably the earliest European example of the class. Once more the archæological phenomena bring home to us the fact that we stand here at the meeting-place of the North and South wind.

ARTHUR J. EVANS.

## THE ASCENT OF MOUNT ST. ELIAS (ALASKA).[1]

THE Italian original of this work was reviewed in our columns a short time ago (see NATURE, May 3), and we now welcome the English translation. In the preface we are informed that "the whole profit on the sale of the Italian edition, together with all royalties and rights on foreign editions, will be dedicated to an Insurance Fund for Italian Guides."

In its present garb the story of the expedition is told in simple and straightforward language, with only here and there an unaccustomed term to show its foreign origin; *e.g.* "In September snow-storms continue almost without *cease*" (p. ix.), and (in reference to rock-systems) "the different components of the *soil* of South Alaska are all stratified" (p. 232). The picturesque passages in the descriptions of the scenery have, however, lost their glow and read somewhat flat, as indeed can scarcely be avoided in a close translation. The distinctiveness of Prof. Israel C. Russell's name seems lost under the unfamiliar initials J. C., which are used throughout the book (except in the appendix, p. 232), although the full name is given correctly on p. 3. Considering the high estimation in which the citizens of San Francisco hold their business energy, it is rather amusing to read Dr. Filippi's impression that their city "being an agricultural centre, is very quiet and exempt from the feverish turmoil of the industrial Eastern States" (pp. 9-10).

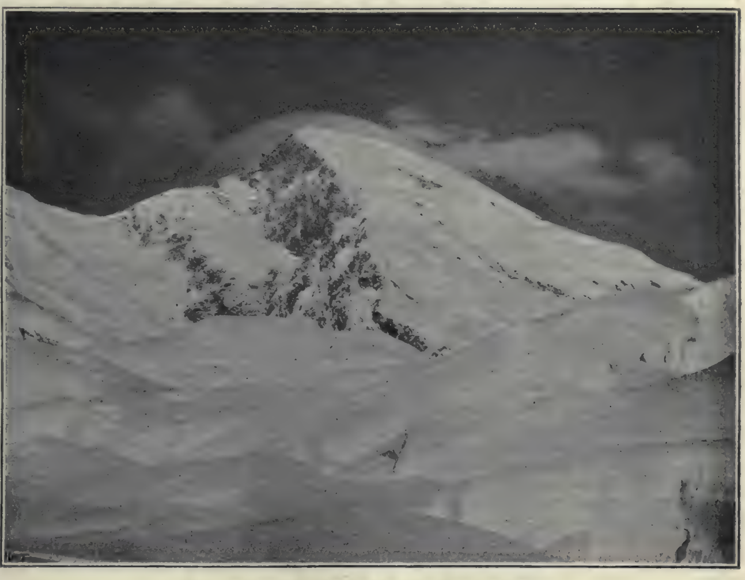

FIG. 1.—Mount St. Elias from the third Newt on Cascade.

The profuse illustrations of the original are all reproduced; and in other respects this English edition is almost, but not quite, as sumptuous as its Italian forerunner. In fact so handsome is it, that in spite of the great mountaineering achievement which it chronicles, one cannot help harbouring, like a well-known essayist under similar circumstances, a lurking desire to strip it of its fine coat to re-clothe some ragged veteran of greater intrinsic consequence.

G. W. L.

## JOHN ANDERSON, M.D., LL.D., F.R.S., &c.

BY the death, on August 15, of Dr. John Anderson, in his sixty-seventh year, a serious loss has been inflicted on zoological science. Amongst the zoologists of this and other countries, Dr. Anderson was widely known and warmly esteemed. The particular branch of inquiry to which for many years before his death he had devoted himself, the investigation of the Vertebrata of Egypt, could only be successfully carried on by a naturalist who, in addition to experience in collecting, had both time and funds at his command, and who also possessed sufficient energy and tact to ensure the assistance of highly-placed Government officials. All these advantages Dr. Anderson combined in an unusual degree, and although it is to be hoped that the work he left unfinished will not be brought to an end by his death, there can be no question that the want of his guiding hand in the enterprise will be severely felt.

---

[1] "The Ascent of Mount St. Elias (Alaska)." By H.R.H. Prince Luigi Amedeo di Savoia, Duke of the Abruzzi; narrated by Filippo de Filippi: illustrated by Vittorio Sella: and translated by Signora Linda Villari with the author's supervision. Pp. xii + 241. 34 photogravure plates, 4 panoramic views, and 117 illustrations in text. (Westminster: Archibald Constable and Co., 1900.)

Dr. Anderson's scientific work consisted of two distinct parts. From 1865 to 1886 he was at the head of the Indian Museum, Calcutta, and chiefly engaged in the collection, arrangement and study of Indian and Burmese Vertebrata. After his retirement from India, in 1886, the subject which occupied him principally, and of late years exclusively, was, as already mentioned, the study of the fauna inhabiting Egypt and the Nile valley.

He was the son of Thomas Anderson, a banker of Edinburgh, and was born on October 4, 1833. His elder brother, Dr. T. Anderson, was in the medical service of the East India Company, became well known as a botanist, and was for some years superintendent of the Botanical Gardens, near Calcutta. After passing through the medical course in the University of Edinburgh, John Anderson received a gold medal and the degree of Doctor of Medicine in 1861. For a couple of years he held the Professorship of Natural Science at the Free Church College, Edinburgh, and he went to Calcutta in 1864.

His arrival in Calcutta was at a fortunate time. The Asiatic Society of Bengal had gradually come into the possession of a large collection, not only of the archæological remains, manuscripts, coins and similar objects, for the study of which the Society was originally established, but also of zoological and geological specimens in large numbers. In the course of the preceding quarter of a century the collections had increased, chiefly through the work of Edward Blyth, the curator, until the Society's premises were crowded, and the Society's funds no longer sufficed for the proper preservation and exhibition of the specimens collected. After long negotiations, interrupted by the disturbances of 1857, arrangements were completed in 1864 by which the archæological and zoological collections of the Society (the geological specimens had been previously transferred) were taken over by the Government of India, who undertook to build a new museum in Calcutta, of which the Society's collections would form the nucleus. The trustees appointed by the Government to manage the new museum asked the Secretary of State for India to select a curator, and Dr. J. Anderson was nominated for the post early in 1865. His status was changed, a few years later, to that of superintendent of the museum, and in addition to his museum work he became Professor of Comparative Anatomy at the Medical College, Calcutta. He held both offices until his retirement from India in 1886.

The time at which Dr. Anderson arrived in India was fortunate in another respect. It coincided with a great impulse given to Indian zoology by the publication of Jerdan's "Birds of India," the last volume of which appeared in 1864, and with the presence in Calcutta of a larger number of men interested in the study of the fauna than were assembled there at any time before or since. Amongst these men were Jerdan himself, Ferdinand Stoliczka, Francis Day, and Valentine Ball, all of whom have now passed away. Probably at no time has so much progress been made in the study of Indian Vertebrata as in the years 1864-74, and in this work Dr. Anderson took an important part.

The new Indian Museum, which now towers over the other buildings of Chowringhee, was not ready for occupation till 1875, but meantime Dr. Anderson had been busily engaged in adding to the zoological collections and in getting them into order. One of his first tasks was the bringing together of an ethnological series, for which the conditions of Calcutta are favourable. Amongst other important additions made by him was that of a fine series of human skulls representing various Indian races. Another very valuable museum series brought together by him consisted of a good collection of Indian Chelonia; skeletons, carapaces and stuffed specimens.

The work in Calcutta was interrupted by two important expeditions to Upper Burma and Yunnan, to both of which Dr. Anderson was attached as naturalist and medical officer. Both expeditions were designed to pass through China to Canton or Shanghai, but in neither case was it found practicable to carry out the original plan. The first expedition, commanded by Colonel E. B. Sladen, left Calcutta at the end of 1867, proceeded as far as Momein in Yunnan, and returned to India in November 1868; the second, under the command of Colonel Horace Browne, left in January 1875, but was treacherously attacked by the Chinese before it had proceeded more than three marches beyond the Burmese frontier, and compelled to return, Mr. Margery, of the Chinese Consular Service, who had been despatched to accompany the mission, and who had preceded it by a march, being murdered with several of his followers. The difficulties experienced by both missions from the time they crossed the frontier between Burma and China, and the opposition of the inhabitants of the country, seriously interfered with zoological observations, and the collection of specimens was generally impossible; but still some important additions were made to the previous knowledge of the fauna. A full account of the journey was given in Dr. Anderson's reports and in a work by him, entitled "Mandalay to Momein," published in 1876. The detailed observations on zoology, supplemented by important notes on some Indian and Burmese mammals and chelonians, were published in 1878-9, under the title of "Anatomical and Zoological Researches, comprising an Account of the Zoological Results of the two Expeditions to Western Yunnan in 1868 and 1875, and a Monograph of the two Cetacean Genera, Platanista and Orcella." The work appeared in two quarto volumes, one consisting of plates. Dr. Anderson was the first who succeeded in obtaining specimens of the porpoise (*Orcella*) inhabiting the Irrawaddi, and the examination of this previously undescribed form led him to make a thorough anatomical investigation of an allied species occurring in the Bay of Bengal and in the estuaries of rivers flowing into the bay, and also of the remarkable cetacean, *Platanista*, inhabiting the Ganges, Brahmaputra and Indus.

The only other important collecting expedition undertaken by Dr. Anderson during his tenure of the superintendentship of the Indian Museum was to Tenasserim and the Mergui Archipelago in 1881-2. This journey was chiefly, though by no means exclusively, undertaken for the collection of marine animals, and the descriptions of the results, to which several naturalists contributed, were published first in the *Journal* of the Linnean Society, and subsequently as a separate reprint in two volumes, under the title of "Contributions to the Fauna of Mergui and its Archipelago." This appeared in 1889. Dr. Anderson's share was the description of the Vertebrata and an account of the Selungs—a curious tribe inhabiting some of the islands; but in connection with his visit to Mergui, and as part of a general description of the fauna which he had at first proposed to publish, he prepared an account of the history of Tenasserim, formerly belonging to Siam. This historical *résumé*, which deals especially with British commercial and political intercourse with Siamese and Burmese ports, was compiled mainly from the manuscript records of the East India Company, preserved in the library of the India Office, and was published in 1889 in a separate volume, entitled "English Intercourse with Siam." The book forms a well-written and interesting chapter of the history of British progress in Southern Asia.

Besides the works already mentioned and many papers, descriptive of mammalia and reptiles, which were published in the *Journal* of the Asiatic Society of Bengal and in the *Proceedings* of the Zoological Society of London, Dr. Anderson wrote two catalogues on very different subjects for the museum under his charge in Calcutta. Of these, one was the first part of the "Catalogue of Mammals," published in 1881, the other the 'Catalogue and Handbook of the Archæological Collection" which appeared in 1883.

Dr. Anderson was elected a Fellow of the Royal Society in 1879, and retired from the Indian Service in 1886. He had married a few years previously, and after retiring he travelled with his wife to Japan. Finally he settled in London, but for the remainder of his life his health was somewhat precarious, and he passed several winters in Egypt. Here he took up the study of the mammals and reptiles, which had received but scant attention since the early part of the century, when the great and superbly illustrated French work on Egypt appeared—a work which, brilliantly begun by Savigny and others, was never adequately completed.

To the work of collecting, examining, figuring and describing the Mammalia, Reptilia and Batrachia of Egypt, the later part of Dr. Anderson's life, when he was well enough for work, was mainly devoted. He also paid some attention to the fauna of the neighbouring countries, and in 1898 published "A Contribution to the Herpetology of Arabia," founded on the collections of the late Mr. J. T. Bent and others. The first part of the important work he had intended to produce on the zoology of Egypt, containing an account of the physical features of the country and descriptions of the Reptilia and Batrachia, appeared in 1898. It is a fine quarto volume with excellent figures, many of them coloured. He had made large collections and notes for the volume on Mammalia, and these it is hoped will be published in due course.

One of the last undertakings in which Dr. Anderson engaged, as soon as the Upper Nile valley was once more thrown open to civilisation, was the systematic collection and description of the fish inhabiting the river and its tributaries. That this important work (of which a notice appeared in NATURE of February 23, 1899) is now being carried out with warm interest and assistance from the Egyptian Government, must be attributed to Dr. Anderson's foresight, zeal and skilful advocacy. Both in our Indian Empire and in North-eastern Africa, Dr. Anderson contributed much to the solution of one of the chief biological questions of the present day, an accurate knowledge of the distribution of animal life.

W. T. B.

## *NOTES.*

A NEW instance of the want of encouragement, and often opposition, which scientific work receives in this country is given by Major Ronald Ross in a letter in Monday's *Times*. It appears from a correspondence just published, that in 1898 the Secretary of State for India refused to permit officers and soldiers to undergo voluntary inoculation against typhoid. It is known to our readers that Dr. Wright, professor of pathology at Netley, elaborated the system of inoculation against typhoid so long ago as 1896. The treatment is based on the soundest scientific principles, and substantial evidence of its value as a preventive measure had been obtained by laboratory experiments. It is entirely free from danger, and there would have been no difficulty in obtaining numerous soldiers to undergo inoculation with Dr. Wright's typhoid vaccine. From the results of the inoculations which might thus have been made three years ago, results would have been obtained which could have been utilised in the recent war in South Africa, and might have been the means of saving hundreds of lives. But unfortunately for the army as well as for science, officers and soldiers appear to have been forbidden to submit themselves for inoculation. In other words, a real success against disease might have been scored, and in any case the information gained would have been of value in making further efforts to diminish mortality from typhoid, but the officials who should have done everything in their power to assist the work, deliberately stopped it by hampering the freedom of the persons who would most benefit by the treatment. It is difficult to understand this singular action, and Major Ross has done a public service by directing attention to it.

IT was announced in NATURE several months ago (p. 230) that Dr. L. Sambon and Dr. G. C. Low, of the London School of Tropical Medicine, had arranged to live from May to the end of October—that is, during the malarial season—in a part of the Roman Campagna, near Ostia, where scarcely a person spends a night without contracting malarial fever of a virulent type. No quinine or other drug was to be taken as a precautionary measure, but the investigators were to live in a mosquito-proof hut from an hour before sunset to an hour after sunrise, so as to avoid being bitten by mosquitoes, which only feed during the night. The experiment was planned to test the reality of the connection between malaria and mosquitoes, and we learn from the *British Medical Journal* that it has been most successful. On September 13, Prof. Grassi visited the residence of the investigators with several other men of science, and gave his testimony as to the value of the experiment in the following telegram to Dr. Manson: "Assembled in British mosquito-proof hut, having verified perfect health experimenters amongst malarial stricken inhabitants, I salute Manson who first formulated mosquito malarial theory.—Grassi." So far as the experiment has gone, therefore, the result is entirely satisfactory, and affords the strongest support to the mosquito theory of malaria. Additional evidence is given by Dr. Elliott, a member of the Liverpool expedition sent to Nigeria some time ago to investigate the subject of malarial fever, who has recently returned to this country. He reports that the members of the expedition have been perfectly well, although they have spent four months in some of the most malarious spots. They lived practically amongst marshes and other places hitherto supposed to be the most deadly, and they attribute their immunity to the careful use of mosquito nets at night.

ANOTHER experiment arranged in connection with their malarial investigation in the Campagna is described in the *British Medical Journal*. Drs. Sambon and Low have shown that by avoiding mosquitoes they avoid malaria; but this is, after all, only negative evidence, and its full value can only be appreciated in connection with the actual production of malaria in a healthy person in this country by the bites of mosquitoes containing the germ of the disease. This evidence is now forthcoming. We learn from our contemporary that a consignment of mosquitoes which had been fed on the blood of a sufferer from malaria in Rome, under the direction of Prof. Bastianelli, was received in London early in July. A son of Dr. Manson, who offered himself as a subject for experiment, allowed himself to be bitten by these insects, and, though he has never been in a malarious country since he was a child, he is now suffering from well-marked malarial infection of double tertian type, and microscopical examination shows the presence of numerous parasites in his blood. Full details of the experiments will be published in due course; meanwhile, they must be regarded as affording the most striking confirmation of the transmission of malaria by mosquito bites that has yet been obtained.

DR. L. A. BAUER, in charge of magnetic work of the U.S. Coast and Geodetic Survey, has gone to Alaska and to the Hawaiian Islands, in order to select the sites for the magnetic observatories in those regions. The principal or standard magnetic observatory is now being erected sixteen miles to the south-east of Washington City, and a fourth observatory is, temporarily, in operation at Baldwin, Kansas. The last named observatory is central to the area being surveyed by four magnetic parties, and it will be shifted about in the western States according to the requirements of the magnetic survey. It is the intention to have the four observatories ready in time to co-operate with the Antarctic expeditions.

IN connection with the usurpation of swallows' nests by house sparrows, Mr. J. H. Allchin sends a description of a swallow-cum-sparrow's nest seen by him at Dymchurch, in the Romney Marsh. The original nest was built on a beam immediately under the corrugated iron roof of a shed, but the usurpers had so completely covered it with straw, grass, feathers, fibres and other materials, that it was almost impossible to see any portion of it. Mr. Allchin remarks: "I have seen other nests of swallows which had been taken possession of by sparrows, but in those instances the only evidences of occupation were bits of straw or grass sticking out of the entrance; this is the first one I have seen covered over so thoroughly as to completely hide the work of the original builders.

ANOTHER successful experiment with electric traction on railways is reported from Germany, the line being from Berlin to Zehlendorf on the new Wannsee railway. The train in question (says *Feilden's Magazine* for September) was equipped as if actually running to scheduled time. It was furnished with a motor car at each end, the work of propulsion being divided equally between them, the advantage claimed for this being that the reversing of the train becomes unnecessary at the end of each journey. Eight ordinary cars were employed in addition, seating in all 400 passengers. These experiments are to be continued over a period of one year, at the termination of which it is expected that the question will be decided whether or not electric propulsion is to be wholly substituted for steam power, while at the same time much useful data will be gathered. An advantage already claimed is that electric motive power is about 15 per cent. cheaper than steam, and also at higher velocities the chance of accidents is supposed to be less. A train of this description is at present on trial in this country, and it will be useful to compare notes from each when the material is available.

FROM all quarters we learn that the present season has been remarkable for the appearance of numerous specimens of the clouded yellow butterflies (*Colias edusa* and *C. hyale*), as well as the holly-blue (*Lycaena argiolus*). During one country walk of three miles in Cambridgeshire, on August 13, the present writer saw three *hyale* and one *edusa*; in a garden near Brighton a holly-blue was seen on September 4, and many collectors report having obtained fair series of one or both of the two yellows in a day's hunting. From *Science Gossip* we learn that the variety *helice* of *C. edusa* has occurred in some numbers in clover fields in east Essex. The year 1892 will be remembered as the last occasion on which *C. edusa* occurred in abundance, but the present season is characterised by the comparative frequency of the pale species *hyale*, which was far less plentiful in 1892. The humming-bird moth (*Macroglossa stellatarum*) appears to have been gaining rather more than the usual notoriety in the daily papers which it has received ever since, some thirty years ago, the late Rev. J. G. Wood, in his "Common British Moths," wrote: "This moth, which is tolerably common, has been very familiar to the public of late years on account of the many letters which have appeared in the daily journals, much to the amusement of practical entomologists, who have been too familiar with the insect in question to think it worth a special notice."

DR. ANTONIO PORTA communicates to the *Rendiconti del R. Istituto Lombardo* certain studies on the anatomy of the common frog-hopper (*Aphrophora spumaria*, L.) having especial reference to the secretion of froth, so well known to all gardeners. The author finds that the apparatus which secretes the frothy liquid in *A. spumaria*, and possibly in other species, consists of hypodermal glands scattered over the back and especially near the stigma, that the *corpus ovalis* is perhaps in relation with the secretion of froth, that the mass of cells found in the latero-ventral position collect and perhaps produce material of which the animal makes use in the elaboration of the secretions, and that the glandular epithelium of the seventh and eighth segments serve as supports for minute appendages of a branchial character, which have disappeared in *Cicadæ* and *Nepa*, thus confirming the hypothesis of Wheeler.

IN view of our knowledge of the influence of radiant energy on electrically charged bodies, much interest attaches to the question whether a solar eclipse has any marked effect on atmospheric electricity. Dr. Julius Elster made observations during the last total eclipse at Algiers, and remarked an important fall of the potential of atmospheric electricity at and slightly after the totality. The observations are given in the last number of the *Memoirs* of the Società degli Spettroscopisti Italiani. On the other hand, Dr. Emilio Oddone describes, in the *Rendiconti del R. Istituto Lombardo*, observations made with an electrometer at Pavia, where during the last eclipse eight-tenths of the solar diameter were obscured. The results were of a negative character. Before the eclipse, high negative potentials were observed, which were attributable to clouds accompanying a distant thunderstorm; but during the eclipse the variations in the electrostatic potential seem to have been similar to the ordinary diurnal variations. It thus appears that the eclipse exercised no very marked influence on the electric state of the air; but whether any portion of the observed variations was attributable to this cause is a question which it would be difficult to answer.

MR. DAVID ROBERTSON has communicated to the *Proceedings* of the Philosophical Society of Glasgow a short note on the equilibrium of a column of air and the atmospheric temperature gradient, in which the adiabatic formula for the maximum gradient consistent with stability is established in a simple manner.

PARTS 10 to 12 of the *Meddelanden från Lunds Astronomiska Observatorium* contain several papers on mathematical astronomy. One, by T. Brodén, deals with some probability considerations relating to the convergence of certain continued fractions, a problem treated by Gyldén in 1898. Certain librations in the planetary system are the subject of a paper by C. V. L. Charlier, while G. Norén and J. A. Wallberg contribute lengthy formulæ for the development of the disturbing function in its canonical elements.

NO. 110 of Ostwald's "Klassiker der exacten Wissenschaften" (Leipzig, Wilhelm Engelmann, 1900) is a reprint of J. H. van 't Hoff's papers on the laws of chemical equilibrium. The three papers in question are those communicated in French to the Swedish Academy of Sciences about the year 1885, and deal with the laws of chemical equilibrium in attenuated systems, a general property of attenuated media, and the electric conditions of chemical equilibrium. The present book is a translation of these papers by Georg Bredig, and an appendix of twenty pages contains a brief biographical notice of van 't Hoff and numerous notes, both historic and explanatory.

IN the course of a paper on the various forms of phosphorescence, in the *Revue Scientifique* for September 8, M. Gustave Le Bon describes a dark lamp ("lampe noire") for the production of invisible radiations of great wave-length in connection with the study of phosphorescence. Among other experiments performed with this lamp, the following is very striking:—In an absolutely dark room, a dark lamp is placed on a table, this lamp not transmitting any trace of visible light. In front of it, M. Le Bon places a statuette covered with sulphide of lime that has been left in darkness for several days, and consequently retains no trace of phosphorescence. After about a couple of minutes the statuette becomes luminous, and appears to emerge from the darkness.

The director of the Meteorological Observatory at Ponta Delgada, St. Michael, has published an interesting report on the proposed establishment of an international meteorological service at the Azores, including a history of the observations in those islands, and a chart showing the tracks of a number of storms which have visited that part of the North Atlantic during the last five years. The first regular observations were made at Angra (Terceira) in 1864, at Ponta Delgada in 1865, and at Santa Cruz (Flores) in 1897. The observations at Ponta Delgada are now regularly published in the Daily Weather Report issued by the Meteorological Council. Since the year 1893 six of the islands have been in telegraphic communication with Lisbon, and eventually cables will be laid to England, Germany, and the United States, and Flores will be connected with the other islands. The direct communication of observations between America, the Azores and this country cannot fail to be most useful both to science and to shipping; and, although the chart above referred to shows that most of the depressions passing the archipelago strike the coasts of Europe considerably south of the British Islands, a knowledge of the positions and movements of the larger areas of high and low barometric pressures in the North Atlantic must be of prime importance for the purpose of storm prediction.

It is well known that while country-folk adhere to the old idea that adders when frightened are in the habit of protecting their young by swallowing them, a large number of naturalists regard the feat as an impossibility. In the September number of *The Zoologist* Mr. G. Leighton, a well qualified anatomist, has set himself the task of ascertaining whether there is any foundation for the objection. And he arrives at the conclusion that there is no anatomical reason why the oft-repeated statement of country observers should not be founded on fact. The author concludes by stating that the objection raised on the ground that the swallowing is unnecessary is a mere matter of opinion, adding that all that is now necessary is for a competent authority to dissect an adder which has been observed to swallow its young. "Until this is done scientific naturalists will continue to regard the question as one capable of proof, if true, but hitherto unproved."

The eminent physiologist Dr. Gustave Loisel has communicated to the *Revue générale des Sciences* of September 15 a long and able letter urging the importance of establishing a course of instruction in practical embryology in the new French Universities. For a considerable time it appears that this subject has been taught to a certain extent in some of these institutions; but, for various reasons, it has not hitherto been made a part of the regular curriculum in all. After pointing out its extreme importance to students of medicine, anatomy, and gynæcology, Dr. Loisel formulates his appeal as follows: (1) That a single course of elementary embryology, embracing both that of man and of other vertebrates, should be established in each University, and that the necessary apparatus should be provided; (2) that this course should be instituted in a manner which would serve the needs of all students to whom a knowledge of this subject is of importance in their future career. These resolutions, we are glad to see, have been unanimously adopted by the Section of Medicine at the recent Congress, and we may therefore hope that this important addition to the teaching of the Universities may shortly be in working order.

We have received vol. vii. pt. 1 of the *Transactions* of the Norfolk and Norwich Naturalists' Society, which contains a number of papers on local topics.

In the *Victorian Naturalist* for August, Mr. A. J. North describes a new genus and species of Australian Passerine bird as *Eremiornis carteri*, while Mr. R. Hall continues his valuable notes on the distribution of the birds of Australia.

We have received the autumn number of *Bibby's Quarterly*, a journal issued at Liverpool ostensibly for the advertisement of certain agricultural and other commodities, but which contains a number of very interesting and well illustrated articles dealing with stock-raising and kindred subjects. Among these, one treating of ostrich-farming should attract general attention.

The September issue of the *Annals* of the South African Museum is devoted to the commencement of a synopsis of the moths of South Africa, by Sir G. F. Hampson. South Africa is the oldest British possession of any considerable size which has hitherto never had a catalogue of its indigenous moths, and as there are now many collectors in the country, Sir George Hampson has been well advised in endeavouring to supply an acknowledged want.

The "British Anti-Dubbing Association" has forwarded to us an influentially signed letter respecting the cruel practice of cutting the combs and wattles of game-fowls. In spite of the fact that the practice is already illegal, and that birds which have been "dubbed" are ineligible for prizes at the British Dairy Farmers' Association show, it is still largely prevalent. It is now hoped that by bringing the matter into prominent notice, the pressure of public opinion may be brought to bear upon the promoters of poultry-shows, so as to disqualify all mutilated birds from being classed.

The present boundaries in North-west Bohemia between the districts in which pure German, pure Tschech (Chekh), and the various mixtures of these languages are spoken, are clearly indicated by Dr. J. Zemmrich on a map in *Globus* (Bd. lxxviii. p. 101) which illustrates his paper on that subject.

The disposal of the dead is an important subject of ethnographical inquiry; therefore thanks from students are due to Mr. W. Crooke for his paper on "Primitive rites of disposal of the dead, with special reference to India," in the *Journal* of the Anthropological Institute (vol. xxix. p. 271). Nearly every form of burial is practised in India, and Mr. Crooke has given full references for every statement he has made.

From Dr. Thurston's report on the administration of the Madras Museum for the year 1899–1900, we learn that the general progress of that institution is satisfactory. Anthropologists will be pleased to hear that the superintendent has found time to continue his valuable investigations concerning the various races met with in the Presidency, those which have recently engaged his attention being the Pathan, Sheik and Saiyad Muhamadans of Madras city.

In the *Abhandlungen der Naturwiss. Gesellsch., Isis*, 1900, Prof. J. Deichmüller describes a find of three broken urns and a stone axe of Neolithic age from near Dresden; these urns and two others described in the paper are decorated with incised lines. The same author also describes a late Slavic cemetery at Niedersedlitz of a date about 1100 of our era. The single measurable skull was meso-orthocephalic, with a cephalic index of about 78·7.

A RECENT number of the *Abhandlungen* of the Vienna Geographical Society consists of an important paper, by Prof. Dr. J. Cvijik, of Belgrade, forming the first part of a study of the glaciation and morphology of parts of Bosnia, Herzegovina and Montenegro. The memoir, which it is impossible to summarise in a note, is illustrated by nine maps.

CHIEF CONSTRUCTOR KRETSCHMER publishes in the *Marine-Rundschau* a paper on the German Antarctic Expedition. The paper deals first with the chief difficulties of Antarctic exploration, the achievements of former expeditions, and the general scheme of work to be undertaken by the expeditions now being fitted out. The second part is of special interest from the minute details and numerous drawings given of the design and construction of the vessel now being built for the German Expedition. We have also received a reprint of Mr. W. S. Bruce's paper in the June number of the *Scottish Geographical Magazine*, giving an account of the proposed Scottish National Antarctic Expedition.

A DESCRIPTIVE catalogue of a collection of the economic minerals of Canada, exhibited at the Paris Exhibition, has been prepared under the direction of Dr. G. M. Dawson. This will be a useful work of reference. It is interesting to note that the collection includes samples of lithographic stone.

THE *Proceedings* of the Geologists' Association for August 1900 contains some highly interesting notes on the geology of the English Lake District, by Mr. J. E. Marr. The notes, which were prepared for the summer excursion of the Association, embody the results of work carried out for many years by Mr. Marr, partly in conjunction with Mr. A. Harker. While supporting the generally accepted views of the succession of the older Palæozoic rocks, the facts now brought forward indicate that the disturbances to which these rocks have been subjected are due to the pushing forward of the strata in a northerly direction *at unequal rates*. Under these conditions the Skiddaw Slates moved furthest forward, causing the Green Slates and Porphyries to "lag behind," and the Upper Slates (Silurian, with Coniston Limestone at base) to lag behind the Green Slates and Porphyries. The peculiar faulting attending these disturbances is specially described. The intrusive igneous rocks and their metamorphic effects and other subjects are also dealt with.

IN the same number of the *Proceedings* there is a paper, by Mr. G. E. Dibley, on zonal features of the chalk pits in the Rochester, Gravesend and Croydon areas. The author has laboured long and enthusiastically in collecting from the various zones, and the results which he now publishes in notes, and in a carefully arranged list of fossils, form an important addition to our knowledge of the life-history of the chalk. An interesting bone, which he obtained from the Middle Chalk of Cuxton, is described by Mr. E. T. Newton as probably belonging to the Rhynchocephalia, a group of lizard-like animals, which includes the living New Zealand *Hatteria* and the Triassic *Hyperodapedon*.

THE *Transactions* of the American Microscopical Society for 1899 (vol. xxi.), contains a number of interesting articles on microscopic objects, zoological and botanical, together with a smaller number on microscope construction and laboratory apparatus.

IN the *Agricultural Gazette* of New South Wales for August, we notice a number of papers of interest and value for farmers and horticulturists in the Colony. Much information is contained in this and in previous numbers on the diseases to which domestic animals and cultivated crops are liable, and on the best methods for their treatment.

THE parts most recently received of Engler's *Botanische Jahrbücher* are Heft 4 of vol. xxviii. and Heft 2 of vol. xxix. Besides a few shorter articles, these parts are almost entirely occupied by two important descriptive papers—a continuation of the editor's report on the results of the German Nyassa expedition, and one by D. Diels on the flora of Central China.

THE *Bulletin* of the Imperial Society of Naturalists of Moscow, No. 4 for 1900, contains several interesting botanical papers in German. Of these the most important is the second of a series by W. Arnoldi on the morphology and history of development of the Gymnosperms. The present paper is devoted to the process of fertilisation in *Sequoia* (*Wellingtonia*), and is a link in the chain of the numerous and most important observations of recent years which connect the process of impregnation in Gymnosperms with that in Vascular Cryptogams on the one hand, and that in Angiosperms on the other hand.

THE third annual dinner of the association of old students of the Central Technical College will be held on Tuesday, October 2nd, at the Restaurant Frascati, Oxford-street. Old students can obtain further particulars from the honorary secretary, Mr. M. Solomon, 12, Edith-road, West Kensington, W., to whom all applications for tickets should be made.

THE three parts of vol. xxxix. of the *Transactions* of the Royal Society of Edinburgh, which have just been issued, contain several very valuable papers read before the Society during the sessions 1897–98 and 1898–99. All the papers have been published separately, and most of them have been reviewed in NATURE, or briefly described in the reports of the meetings of the Society.

MESSRS. BAILLIÈRE, TINDALL AND COX have published the fifth edition of "A Synopsis of the British Pharmacopœia," compiled by Mr. H. Wippell Gadd, with analytical notes and suggested standards by Mr. C. G. Moor. This little pocket-book is widely appreciated: it contains a complete table of chemicals, drugs and preparations in the official "Pharmacopœia," with their character, doses, &c., as well as other information arranged in a convenient form.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*, ♀) from West Africa, presented by Mrs. C. Campbell; a Red-footed Ground Squirrel (*Xerus erythropus*) from West Africa, presented by Dr. Oswald Horrocks; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Captain W. H. Rotheram, R.E.; a Plantain Squirrel (*Sciurus plantani*) from Java, presented by Mr. H. H. Goodwin; two Dusky Ducks (*Anas obscura*) from North America, presented by Mr. W. H. St. Quintin; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. A. L. Jessopp; three Jays (*Garrulus glandarius*), British, presented by Dr. R. B. Sharpe; four Pheasants (*Phasianus colchicus*), British, presented by Mr. F. Larratt; two Western Yellow-winged Laughing Thrushes (*Trochalopterum nigrimentum*), a Rufous-chinned Laughing Thrush (*Ianthocincla rufigularis*), a Slaty-headed Scimitar Babbler (*Pomatorhinus schisticeps*), a Black-throated Ouzel (*Merula strigularis*), two Tickell's Ouzels (*Merula unicolor*), a Spotted wing (*Psaroglossus spiloptera*) from British India, presented by Mr. E. W. Harper; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by Mr. Randolph Berens; a Red Tiger Cat (*Felis chrysothrix*), a Leopard (*Felis pardus*), two Rose-ringed Parrakeets (*Palaeornis docilis*) from West Africa, a Yellow-crowned Troupial (*Icterus chrysocephalus*), a Yellow-backed Troupial (*Icterus croconotus*) from South America, an Alpine Marmot (*Arctomys marmotta*), two Crossbills (*Loxia curvirostra*), European; ten Elephantine Tortoises (*Testudo elephantina*) from the Aldabra Islands, deposited.

## OUR ASTRONOMICAL COLUMN

ASTRONOMICAL OCCURRENCES IN OCTOBER.

Oct. 6. 13h. 35m. to 14h. 29m. Moon occults κ Piscium (mag. 5).
9. 10h. 42m. Minimum of Algol (β Persei).
11. 6h. 51m. Transit (egress) of Jupiter's Sat. III.
11. 8h. 47m. to 9h. 25m. Moon occults $\omega^2$ Tauri (mag. 4·6).
12. 7h. 30m. Minimum of Algol (β Persei).
12. 18h. 36m. to 19h. 23m. Moon occults ζ Tauri (mag. 3).
13. 15h. to 15h. 43m. Moon occults ν Geminorum (mag. 4).
15. Venus. Illuminated portion of disc = 0·637.
15. Mars. ,, ,, ,, = 0·902.
16. 17h. 26m. to 18h. 30m. Moon occults κ Cancri (mag. 5).
17. Saturn. Outer minor axis of outer ring = 16″·68.
19. 10h. Conjunction of Jupiter and Uranus. Jupiter, 0° 25′ N.
19–21. Epoch of Orionid meteoric shower. (Radiant 91° + 15°.)
26. 12h. Conjunction of Jupiter and moon. Jupiter, 0° 27′ S.
28. 6h. 21m. Jupiter's Sat. IV. in conjunction S. of planet.
28. Probable date of perihelion of Barnard's comet (1884 II.).
29. 8h. 27m. to 8h. 46m. Moon occults *d* Sagittarii (mag. 4·9).
29. 16h. Mercury at greatest elongation (23° 46′ E.).

THE FIREBALL OF SUNDAY, SEPTEMBER 2, 6h. 54m.—A very large number of observations of this brilliant object were made, but they were not very exact, as the meteor appeared in daylight. The radiant point was probably in Cepheus at about 334° + 57°. The object, during its visible flight, appears to have descended from a height of eighty-five miles over Richmond, Yorks., to twenty miles over Fleetwood, Lancs., and to have traversed a path of eighty-four miles. Another fine meteor was observed on Sunday evening, September 16, at 8h. 44m., and descriptions have come from London, Birmingham, Oxford and Llanelly. The radiant was in the southern sky between Capricornus and Piscis Australis at 324° − 25°. The meteor fell from about fifty miles over Bewdley to thirty-two miles over Wigan, and had a visible course of eighty-six miles. The velocity is somewhat doubtful.

EPHEMERIS FOR OBSERVATIONS OF EROS:—

| 1900. | | R.A. h. m. s. | | Decl. ° ′ ″ |
|---|---|---|---|---|
| Sept. 27 | ... | 2 43 7·41 | ... | +43 27 2·0 |
| 28 | ... | 43 25·24 | ... | 43 49 43·2 |
| 29 | ... | 43 40·01 | ... | 44 12 20·4 |
| 30 | ... | 43 51·63 | ... | 44 34 52·7 |
| Oct. 1 | ... | 43 59·96 | ... | 44 57 18·9 |
| 2 | ... | 44 4·92 | ... | 45 19 38·2 |
| 3 | ... | 44 6·44 | ... | 45 41 50·2 |
| 4 | ... | 2 44 4·44 | ... | +46 3 53·8 |

The co-operative observations for determinations of parallax will commence about the beginning of October. The planet is at present in the constellation Perseus, and passes the meridian of London about 2·40 a.m.

EPHEMERIS OF COMET BORRELLY-BROOKS (1900*b*).—This comet is now rapidly becoming fainter, and the following abridgment from a complete Ephemeris furnished by Herr A. Scheller (*Astronomische Nachrichten*, Bd. 153, Nos. 3660, 3663) will doubtless suffice for observers possessed of the necessary optical power:—

*Ephemeris for 12h. Berlin Mean Time.*

| 1900. | | R.A. h. m. s. | | Decl. ° ′ | | Br. |
|---|---|---|---|---|---|---|
| Sept. 29 | ... | 14 26 34 | ... | +69 7·7 | ... | 0·07 |
| Oct. 3 | ... | 32 53 | ... | 68 11·0 | ... | ·06 |

AUTOMATIC PHOTOGRAPHY OF THE CORONA.—Mention has often been previously made of Prof. C. Burckhalter's ingenious apparatus for obtaining photographs of the solar corona during an eclipse, and it now appears that he was extremely successful at the eclipse in May last. *Popular Astronomy*, vol. viii., contains reproductions from two negatives of the corona secured by him, one uncontrolled as has hitherto been usual, the other the result of intercepting part of the coronal light for varying periods of time during the total exposure. The total exposure in each case was 8·0 seconds, but by means of a system of revolving diaphragms arranged in one of the cameras, the image was shielded in various regions for different times, thus permitting the details of the inner corona to be photographed on the same plate as the outermost faint streamers. The following are the calculated effective exposures at the several stated distances from the moon's centre (moon's semi-diameter = 15′ 58″).

| Distance from moon's centre | 16′ | ... | 20′ | ... | 32′ | ... | 50′ | ... | 110 |
|---|---|---|---|---|---|---|---|---|---|
| Exposure | ... 0·04s. | ... | 0·23s. | ... | 1·76s. | ... | 3·20s. | ... | 8·00s. |

The photograph shows the inner coronal detail close to the limb of the moon, the outer streamers extending for more than a lunar diameter. Several of the inner coronal tufts appear to be projected on the long broader streamers as background.

---

## THE IRON AND STEEL INSTITUTE.

THE Iron and Steel Institute held its autumn meeting in Paris on September 18 and 19, under the presidency of Sir William Roberts-Austen, K.C.B., F.R.S. Besides a long programme of ten papers, visits to the Exhibition, to the works at St. Chamond, at Hayange in Lorraine, and at St. Denis near Paris, were arranged by an influential reception committee, of which Mr. Robert de Wendel was president and Mr. Henri Vastin honorary secretary. The attendance was unusually large, and the meeting was in every respect a successful one. The proceedings began on September 18 at the house of the Société d'Encouragement, with an address of welcome by Mr. Robert de Wendel, president of the French Association of Ironmasters. Sir William Roberts-Austen, having acknowledged the welcome, delivered a presidential address dealing in faultless literary style with the history of metallurgy in France.

The first paper read by the secretary, Mr. Bennett Brough, was by Mr. H. Pinget, secretary of the Comité des Forges, and dealt with the development of the iron industry in France since the Institute's last visit to Paris in 1889. The increase in output of iron and steel has been much greater than it was in the interval between the two previous exhibitions in Paris. No striking technical invention has been made, but great progress has been effected in increasing the power of the appliances used and in improving the quality of the products. There is a marked tendency to replace cast iron by cast steel, and success has attended endeavours to cast complicated forms in metal which is both tough and of high tensile strength. Moreover, special steels are now available for the requirements of particular applications, such as the growing exigencies of armour plate. The discussion on this paper was confined to complimentary remarks from Sir Lowthian Bell, F.R.S., Mr. Greiner and others.

The second paper, the most important submitted to the meeting, was that by Mr. J. E. Stead on iron and phosphorus. It is typical of modern metallurgical research, and contains a mass of original observations showing how phosphorus occurs in iron and steel. The subject is dealt with in four sections: (1) the constitution, properties and microstructure of iron containing form traces to 24 per cent. of phosphorus; (2) the effect of carbon when introduced by the fusion or cementation process into iron containing phosphorus; (3) the microstructure of pig iron containing phosphorus; and (4) the diffusion of solid phosphide of iron into iron. There are appended to the paper useful notes on eutectics, on solid solutions, on the method of determining free phosphide of iron in iron and steel, and on heat-tinting metal sections for microscopic examination. The observations recorded show that iron will retain as much as 1·75 per cent. of phosphorus as phosphide in solid solution, and that when more than that is present, the excess separates and is found as free phosphide of iron mixed up with the mass of iron. It is also shown that carbon added to solid solutions of phosphorus in iron throws out of solution the dissolved phosphide, which appears in a separate state. The most remarkable result given indicates that when carbon is added by the cementation process, the phosphide, when in large quantity, is thrown, not only out of solution, but escapes entirely out of the metal as a liquid eutectic leaving a constant residuum behind. A method is described by which phosphorus compounds in pig iron can be identified by means of the microscope. This consists in simply heating the polished surfaces to about 300° C. for a few minutes, when each constituent takes a different oxidation tint. The iron acquires a sky-blue colour, the carbide a red-brown and the phosphide compound a pale yellow. The coloured sections are of great beauty. Many results are given showing how the solid phosphide diffuses in solid iron, and showing that under suitable conditions well-formed crystals will grow in solid metal.

Mr. H. Bauerman's paper on iron and steel at the Universal Exhibition, Paris, 1900, was prepared mainly for the use of the members of the Institute visiting the Exhibition during the meeting. It contained a critical description of the more prominent metallurgical exhibits, and forms a valuable record of the condition of the metallurgical industry at the close of the century.

On September 19, the remaining papers on the programme were dealt with. Chief among these was that by Mr. E. F. Lange, on a new method of producing high temperatures. The principle underlying the process, which is the outcome of researches made by Dr. H. Goldschmidt of Essen, is not new, as it is based upon the heat energy developed by the chemical action of aluminium upon oxygen, or rather that between aluminium and certain metallic oxides. The practicability of the process was clearly shown by the welding together during the meeting of two short lengths of heavy girder rails. The method not only opens up a new field for aluminium but also promises to be of considerable importance in engineering work. In the discussion Sir William Roberts-Austen pointed out the extreme precision with which the reduction took place, and Sir Lowthian Bell dwelt on the value of the process if it should prove that carbonless iron could be obtained by it for electrical purposes.

The paper by Mr. A. L. Colby, of Bethlehem, United States, on American standard specifications and methods of testing iron and steel, embodied the results of over a year's work by a committee of American experts, conducted with a view to the adoption of international standards. Some of the specifications were criticised by Mr. R. A. Hadfield. The engineer, he thought, was encroaching on the field of the metallurgist. Interesting contributions to the discussion were made by Mr. C. P. Sandberg and by Dr. Dudley, of Pennsylvania.

In a paper on the influence of aluminium on the carbon in cast-iron, Mr. G. Melland and Mr. H. W. Waldron gave the results of an elaborate research in which they endeavoured to determine the amount of aluminium which is necessary to produce the maximum separation of graphite in a white pig-iron as free as possible from silicon and other impurities, and to ascertain, by casting every melting both in sand and in chill moulds, the effect produced by slow and rapid cooling upon the mode of existence of the carbon in the metal with amounts of aluminium varying from 0·02 to 12 per cent.

In the paper by Mr. Louis Katona, of Resicza, Hungary, the various disadvantages of the rolling-mills now in use were discussed, and suggestions were made for obviating them with a view to increasing the output and lessening the fuel consumption.

In a lengthy paper on the constitution of slags, which was taken as read, Baron H. von Jüptner discussed iron slags from a modern point of view, and described the varying reactions which take place between them and iron. The slags considered are divided into three groups—silicate slags, phosphate slags and oxide slags. The results of the investigation tend to show that slags should be regarded as solutions, and not as complicated chemical compounds.

The "phase-rule" of Gibb has served as a guide to the authors of two well-reasoned papers of great scientific interest—one on iron and steel from the point of view of the phase doctrine, by Prof. Bakhuis-Roozeboom, of Amsterdam, and the other on the present position of the solution theory of carburised iron, by Dr. A. Stansfield. The phase rule says in effect that in a system such as that of the carburised irons, in which two distinct substances (carbon and iron) are involved, but in which certain forms or phases of carbon or iron, or carbon-iron solution, or carbon-iron compound, are present, no more than two of these phases can exist in equilibrium with each other at a particular temperature. In the case of a solution of salt in water, this would mean that there could only be salt and ice and solution together at a particular temperature (the eutectic temperature), and that at any other temperature there could only be ice and solution or salt and solution (at temperatures above the eutectic), or ice and salt (at temperatures below the eutectic). In the case of a salt solution this is quite evident, but the value of the phase rule is that we can apply it with equal confidence in cases where we do not, to begin with, know the answer to our question. Applying the rule to the case of solid carburised iron at temperatures above that of all the known allotropic charges—we have the four possible substances of iron, graphite, cementite and solid solution of carbon (either graphite or cementite) in pig-iron. The rule states that only two of these can in general exist permanently together. The general conclusions to be drawn from Dr. Stansfield's researches are :—

(1) That carbon is less soluble in iron when presented in the form of graphite than when presented in the form of cementite.

(2) That the apparent reversal of this in steel is due partly to the absence of nuclei of graphite on which further deposits might take place ; partly to the length of time required for the separation of the graphite, involving, as it does, the gradual passage of carbon through the iron to reach the nuclei, and partly to the mechanical pressure which must oppose the formation of graphite in solid steel.

The meeting was brought to a close by a vote of thanks to the French authorities and societies, whose hospitality had been enjoyed, proposed by the president and seconded by Mr. W. Whitwell, president-elect. A vote of thanks to the president was proposed by Mr. Greiner, of Seraing, Belgium, and seconded by Mr. Nordenfelt. The social functions in connection with the meeting were of a very attractive character. They included an operatic entertainment organised by the Comité des Forges, a reception by the Commissioner-General and Mrs. Jekyll at the British Royal Pavilion, a banquet at the Hôtel Continental, a reception by Mr. E. Schneider in the Le Creusot pavilion, a reception at the Hôtel de Ville by the president of the Municipal Council, and a reception on September 24 by the Minister of Public Works.

---

## *THE BRADFORD MEETING OF THE BRITISH ASSOCIATION.*

### SECTION K.

### BOTANY.

OPENING ADDRESS BY PROF. S. H. VINES, M.A., D.SC., F.R.S., PRESIDENT OF THE SECTION.

THERE has been considerable difference of opinion as to whether the present year marks the close of the nineteenth or the beginning of the twentieth century. But whatever may be the right or the wrong of this vexed question, the fact that the year-date now begins with 19, instead of with 18, suggests the appropriateness of devoting an occasion such as the present to a review of the century which has closed, as some will have it, or, in the opinion of others, is about to close. I therefore propose to address you upon the progress of Botany during the nineteenth century.

I am fully conscious of the magnitude of the task which I am undertaking, more especially in its relation to the limits of time and space at my disposal. So eventful has the period been that to give in any detail an account of what has been accomplished during the last hundred years would mean to write the larger half of the entire history of Botany. This being so, it might appear almost hopeless to attempt to deal with so large a subject in a Presidential Address. But I trust that the very restrictions under which I labour may prove to be rather advantageous than otherwise, inasmuch as they compel me to confine attention to what is of primary importance, and thus to give special prominence to the main lines along which the development of the science has proceeded.

### *Statistics.*

We may well begin with what is, after all, the most fundamental matter, viz. the relative numbers of known species of plants at the beginning and at the end of the century. It might appear that the statistics of plants was a subject susceptible of very simple treatment, but unfortunately this is not the case. It must be remembered that a "species" is not an invariable standard unit, like a pound or a pint, but that it is an idea dependent upon the subjectivity of individual botanists. For instance, one botanist may regard a certain number of similar plants as all belonging to a single species, whilst another may find the differences among them such as to warrant the distinction of as many species as there are plants. It is this inevitable variation in the estimation of specific characters which renders it difficult to deal satisfactorily with plants from the statistical point of view. However, the following figures may be regarded as giving a fair idea of the increase in the number of "good" species of living plants.

It is generally stated that about 10,000 species of plants were known to Linnæus in the latter half of the eighteenth century, of which one-tenth were Cryptogams; but so rapid was the progress in the study of new plants at that time that the first enumeration of plants published in the nineteenth century, the "Synopsis" of Persoon (1807), included as many as 20,000 species of Phanerogams alone. Turning now to the end of the century, we arrive at the following census, for which I am indebted mainly to Prof. Saccardo (1892) and to Prof. de Toni who has kindly given me special information as to the Algæ:—

*Species of Phanerogams indicated in Bentham and Hooker's "Genera Plantarum" (Durand, "Index," 1888).*

| | |
|---|---|
| Dicotyledons ... ... ... ... ... | 78,200 |
| Monocotyledons ... ... ... ... | 19,600 |
| Gymnosperms ... ... ... ... ... | 2,420 |
| | 100,220 |
| Estimated subsequent additions (Saccardo) ... | 5,011 |
| Total Phanerogams ... | 105,231 |

*Species of Pteridophyta (indicated in Hooker and Baker's "Synopsis"; Baker's "New Ferns" and "Fern Allies").*

| | |
|---|---|
| Filicinæ (including Isoëtes), about ... ... | 3,000 |
| Lycopodinæ, about ... ... ... ... | 432 |
| Equisetinæ, about ... ... ... ... | 20 |
| Total Pteridophyta ... ... | 3,452 |

*Species of Bryophyta (Saccardo's Estimate).*

| | |
|---|---|
| Musci ... ... ... ... ... ... | 4,609 |
| Hepaticæ ... ... ... ... ... | 3,041 |
| Total Bryophyta ... ... | 7,650 |

*Species of Thallophyta.*

| | |
|---|---|
| Fungi (including Bacteria) (Saccardo) ... | 39,663 |
| Lichens (Saccardo) ... ... ... ... | 5,600 |
| Algæ (incl. 6000 Diatoms) (de Toni)... ... | 14,000 |
| Total Thallophyta ... ... | 59,263 |

Adding these totals together—

| | |
|---|---|
| Phanerogams ... ... ... ... | 105,231 |
| Pteridophyta ... ... ... ... ... | 3,452 |
| Bryophyta ... ... ... ... ... | 7,650 |
| Thallophyta ... ... ... ... ... | 59,263 |
| we have a grand total of ... ... ... ... | 175,596 |

as the approximate number of recognised species of living plants.

These figures are sufficiently accurate to show how vast have been the additions to the knowledge of plants in the period under consideration, and they afford much food for thought. In the first place, they indicate how closely connected has been the growth of this branch of Botany with the exploration and opening-up of new countries which has been so characteristic a feature of the century. Again, no one can consider these figures without being struck by the disparity in the numbers of species included in the different groups; a most interesting topic, which cannot, however, be entered upon here. It must suffice to point out in a general way that the smaller groups represent families of plants which attain their numerical zenith in long past geological periods, and are now decadent, whilst the existing flora of the world is characterised by the preponderating Angiosperms and Fungi.

We may venture to cast a forward glance upon the possible future development of the knowledge of species. Various partial estimates have been made as to the probable number of existing species of this or that group, but the only comprehensive estimate with which I am acquainted is that of Prof. Saccardo (1892). He begins with a somewhat startling calculation to the effect that there are at least 250,000 existing species of Fungi alone, and he goes on to suggest that probably the number of species belonging to the various other groups would amount to 150,000; hence the total number of species now living is to be estimated at over 400,000. On the basis of this estimate it appears that we have not yet made the acquaintance of half the contemporary species; so that there remains plenty of occupation for systematic and descriptive botanists, especially in the department of Fungology. It is also rather alarming, in view of the predatory instincts of so many of the Fungi, to learn that they constitute so decided a majority of the whole vegetable kingdom.

In spite of the great increase in the number of known species, it cannot be said that any essentially new type of plant has been discovered during the century. So far as the bounds of the vegetable kingdom have been extended at all, it has been by the annexation of groups hitherto regarded as within the sphere of influence of the zoologists. The most notable instance of this has occurred in the case of the Bacteria, or Schizomycetes, as Naegeli termed them. These organisms, discovered by Leeuwenhoek 200 years ago, had always been regarded as infusorian animals until, in 1853, Cohn recognised their vegetable nature and their affinity with the Fungi. These plants have acquired special importance, partly on account of the controversy which arose as to their supposed spontaneous generation, but more especially on account of their remarkable zymogenic and pathogenic properties, so that Bacteriology has become one of the new sciences of the century.

### *Classification.*

Having gained some idea of the number of species which have been recognised and described during the century, the next point for consideration is the progress made in the attempt to reduce this mass of material to such order that it can be intelligently apprehended; in a word, to convert a mass of facts into a science; "Filum ariadneum Botanices est systema, sine quo chaos est Res Herbaria" (Linnæus).

The classification of plants is a problem which has engaged attention from the very earliest times. Without attempting to enter into the history of the matter, I may just point out that, speaking generally, all the earlier systems of classification were more or less artificial, the subdivisions being based upon the distinctive features of one set of members of the plant. When I say that of all these systems that proposed by Linnæus (1735) was the most purely artificial, I do not imply any reproach: if it was the most artificial, it was at the same time the most serviceable, and its author was fully aware of its artificiality. This system is generally regarded as his most remarkable achievement; but the really great service which Linnæus rendered to science was the clear distinction which he for the first time drew between systems which are artificial and those which are natural. Recognising, as he did, his inability to frame at that period a satisfactory natural system, he also realised that with the increased number of known plants some more ready means of determining them was an absolute necessity, and it was for this purpose that he devised his artificial system, not as an end, but as a means. The end to be kept in view was the natural classification: "Methodus naturalis est ultimus finis Botanices" is his clearly expressed position in the "Philosophia Botanica."

There is a certain irony in the fact that the enthusiastic acceptance accorded to his artificial system throughout the greater part of Europe contributed to postpone the realisation of Linnæus's cherished hopes with regard to the attainment of a natural classification. It was just in those countries, such as Germany and England, where the Linnean system was most readily adopted that the development of the natural system proceeded most slowly. It was in France, where the Linnean system never secured a firm hold, that the quest of the natural system was pursued; and it is to French botanists more particularly that our present classification is due. It may be traced from its first beginnings with Magnol in 1689, through the bolder attempts of Adanson and of Bernard de Jussieu (1759), to the relatively complete method propounded by Antoine Laurent de Jussieu in his "Genera Plantarum," just 100 years later.

The nineteenth century opened with the struggle for predominance between the Jussiean and the Linnean systems. In England the former soon obtained considerable support, notably that of Robert Brown, whose "Prodromus Floræ Novæ Hollandiæ," published in 1810, seems to have been the first English botanical work in which the natural system was adopted; but it did not come into general use until it had been popularised by Lindley in the 'thirties.

Meantime the Jussiean system had been extended and improved by Auguste Pyrame de Candolle (1813–24). It is essentially the Candollean classification which is now most generally in use, and it has been immortalised by its adoption in Bentham and Hooker's "Genera Plantarum," one of the great botanical monuments of the century. In Germany, however, it has been widely departed from, the system there in vogue being based upon Brongniart's modification (1828, 1850) of de Candolle's method as elaborated successively by Alex. Braun (1864), Eichler (1876–83) and Prof. Engler (1886, 1898). It must be admitted that for the last fifty years the further evolution of the natural system, at any rate so far as Phanerogams are concerned, has been confined to Germany.

One of the most important advances in the classification of Phanerogams was based upon Robert Brown's discovery in 1827 of the gymnospermous nature of the ovule in Conifers and Cycads, which led Brongniart (1828) to distinguish these plants as "Phanérogames gymnospermes"; and although the systematic position of these plants has since then been the subject of much discussion, the recognition of the Gymnospermæ as a distinct group of archaic Phanerogams is now definitely accepted.

Moreover, the greatly increased knowledge of the Cryptogams has involved a considerable reconstruction in the classification of that great sub-kingdom. One of the most striking discoveries is that first definitely announced by Schwendener (1869) concerning Lichens, to the effect that the body of a Lichen consists of two distinct organisms, an Alga and a Fungus, living in symbiosis; a discovery which was so nearly made by other contemporary botanists, such as de Bary, Berkeley and Sachs, and which can be traced back to Haller and Gleditsch in the eighteenth century.

But the discoveries which most affected the classification of the Cryptogams are those relating to their reproduction. Whilst it had been recognised, almost from time immemorial, that Phanerogams reproduce sexually, sexuality was denied to Cryptogams until the observations on Liverworts and Mosses by Schmidel and by Hedwig (of whom it was said that he was born to banish Cryptogamy) in the eighteenth century; and even as late as 1828 we find Brongniart classifying the Fungi and Algæ together as "Agames." But in the middle third of the nineteenth century, by the labours of such men as Thuret, Pringsheim, Cohn, Hofmeister, Naegeli and de Bary, the sexuality of all classes of Cryptogams was clearly established. It is worthy of note that, although the sexuality of the Phanerogams had been accepted for centuries, yet the details of sexual reproduction were first investigated in Cryptogams. For it was not until 1823 that Amici discovered the pollen-tube, and it was more than twenty years later (1846) before he completed his discovery by ascertaining the true significance of the pollen-tube in relation to the development of the embryo; whilst it remained for Strasburger to observe, thirty years later, the actual process of fertilisation.

The discovery of the reproductive processes in Cryptogams not only facilitated a natural classification of them, but had the further very important effect of throwing light upon their relation to Phanerogams. Perhaps the most striking botanical achievement of the nineteenth century has been the demonstration by Hofmeister's unrivalled researches (1851) that Phanerogams and Cryptogams are not separated, as was formerly held, by an impassable gulf, but that the higher Cryptogams and the lower Phanerogams are connected by many common features.

The development of the natural classification, of which an account has now been given, proceeded for the most part on the assumption of the immutability of species. As Linnæus expressed it in his "Fundamenta Botanica," "species tot numeramus, quot diversæ formæ in principio sunt creatæ." It is difficult to understand how, with this point of view, the idea of affinity between species could have arisen at all; and yet the establishment of genera and the attempts at a natural system prove that the idea was operative. The nature of the prevalent conception of affinity is well conveyed by Linnæus's aphorism, "Affines conveniunt habitu, nascendi modo, proprietatibus, viribus, usu."

But a conviction had been gradually growing that the assumed fixity of species was not well founded, and that, on the contrary, species are descended from pre-existent species. This view found clear expression in Lamarck's "Philosophie Zoologique," published early in the century (1809), but it did not strongly affect public opinion until after the publication of Darwin's "Origin of Species" in 1859. Regarded from this point of view, the problems of classification have assumed an altogether different aspect. Affinity no longer means mere similarity, but blood-relationship depending upon common descent. We no longer seek a "system" of classification; we endeavour to determine the mutual relations of plants. The effect of this change has been to stimulate the investigation of plants in all their parts and in all stages of their life, so as to attain that complete knowledge of them without which their affinities cannot be accurately estimated. If the classification of Cryptogams is, at the present moment, in a more satisfactory position than that of Phanerogams, it is just because the study of the former group has been, for various reasons, more thorough and more minute than that of the latter.

### *Palaeophytology.*

The stimulating influence of the new doctrine was not, however, confined to the investigation of existing plants; it also gave a remarkable impulse to the study of fossil plants, inasmuch as the theory of descent involves the quest of the ancestors of the forms that we now have around us. Marvellous progress has been made in this direction during the nineteenth century, by the labours more especially of Brongniart, Goeppert, Unger, Schimper, Schenck, Saporta, Solms-Laubach, Renault, on the Continent, and in our own country of Lindley and Hutton, Hooker, Carruthers, and more especially of Williamson. So far-reaching are the results obtained that I can only attempt the barest summary of them. I may perhaps best begin by saying that only a small proportion of existing species have been found in the fossil state. In illustration I may adduce the statement made by Mr. Clement Reid in his recent work, "The Origin of the British Flora," that only 270 species, that is, about one-sixth of the total number of British vascular plants, are known as fossils. Making all due allowances for the imperfection of the geological record, for the limited area investigated, and for the difficulty of determination of fragmentary specimens, it may be stated generally that the number of existing species has been found to rapidly diminish in the floras of successively older strata; none, in fact, have been certainly found to persist beyond the Tertiary period. Certain existing genera, belonging to the Gymnosperms and to the Pteridophyta, have, however, been traced far down into the Mesozoic period. Similarly, the distribution in time of existing natural orders does not coincide with that of existing genera; thus the Ferns of the Carboniferous epoch apparently belong, for the most part, if not altogether, to the order Marattiaceæ, but they are not referable to any of the existing genera.

Moreover, altogether new families of fossil plants have been discovered: such are, among Gymnosperms, the Cordaitaceæ and the Bennettitaceæ; among Pteridophyta, the Calamariaceæ, the Lepidodendraceæ, the Sphenophyllaceæ and the Cycadofilices. It is of interest to note that all these newly discovered families can be included within the main subdivisions of the existing flora; in fact, no fossil plants have been found which suggest the existence in the past of groups outside the limits of our Phanerogamia, Pteridophyta, Bryophyta and Thallophyta.

It cannot be said that the study of Palæobotany has as yet made clear the ancestry and the descent of our existing flora. To begin with the angiospermous flowering plants, it has been ascertained that they make their first appearance in the Cretaceous epoch, but we have no clue as to their origin. The relatively late appearance of Angiosperms in geological time suggests that they must have sprung from an older group, such as the Gymnosperms or the Pteridophyta; but there is no evidence to definitely establish either of these possible origins. Then as to the origin of the Gymnosperms, whilst it cannot be doubted that they were derived from the Pteridophyta, the existing data are insufficient to enable us to trace their pedigree. The most ancient family of Gymnosperms, the Cordaitaceæ, can be traced as far back as any known Pteridophyta, and cannot, therefore, have been derived from them; but the fact that the Cordaitaceæ exhibit certain cycadean affinities, and the discovery of the Cycadofilices, suggest that what may be termed the cycadean phylum of Gymnosperms (including the Cordaitaceæ, Bennettitaceæ, Cycadaceæ, and perhaps the Ginkgoaceæ) had its origin in a filicineous ancestry, of which, it must be admitted, no forms have as yet been recognised.

Turning to the Pteridophyta, the origin of the Ferns is still quite unknown: the one fact which seems to be clear is that the eusporangiate forms (Marattiaceæ) are more primitive than the leptosporangiate. With regard to the Equisetinæ, the Calamariaceæ were no doubt the ancestors of the existing and of the fossil Equisetums. Similarly, in the Lycopodinæ, the palæozoic Lepidodendraceæ were the forerunners of the existing Lycopodiums and Selaginellas. The discovery of the Sphenophyllaceæ seems to throw some further light upon the phylogeny of these two groups, inasmuch as these plants possess characters which indicate affinity with both the Equisetinæ and the Lycopodinæ, thus suggesting the possibility that they may have sprung from the same ancestral stock.

To complete the geological survey of the vegetable kingdom I will briefly allude to the Bryophyta and the Thallophyta. Owing no doubt to their delicate texture, the records of these plants have been found to be very incomplete. So much is this the case with the Bryophyta that I forbear to make any statement concerning them. The chief point of interest with regard to the Fungi is that most of those which have been discovered in the fossil state were found in the tissues of woody plants on which they were parasitic. In this way it has been possible to ascertain, with some probability, the existence of Bacteria and of mycelial Fungi in the Palæozoic period. The records of the Algæ are more satisfactory; they have been traced far back into the Palæozoic age, where they are represented by siphonaceous forms and by the somewhat obscure plants known as *Nematophycus* and *Pachytheca*.

In a general way the study of Palæobotany has proved the development of higher from lower forms in the successive geological periods. Thus the Tertiary and Quaternary periods are characterised by the predominance of Angiosperms, just as the Mesozoic period is characterised by the predominance of Gymnosperms, and the Palæozoic by the predominance of Pteridophyta. And yet, as I have been pointing out, we are not able to trace the ancestry of any one of the larger groups of plants. The chief reason for this is that the geological record, so far as it is known, has been found to break off with such surprising abruptness that the earliest, and therefore the most interesting, chapters in the evolution of plants are closed to us. After the wealth of plant-forms in the Carboniferous epoch there is a striking falling-off in the Devonian, in which, however, plants of high organisation, such as the Cordaitaceæ, the Calamariaceæ and the Lepidodendraceæ, still occur. In the Silurian epoch vascular plants are but sparingly present—but it is remarkable that any such highly organised plants should be found there—together with probable Algæ, such as *Nematophycus* and *Pachytheca*. The Cambrian rocks present nothing but so-called "Fucoids," such as *Eophyton*, &c., some of which may be Algæ. The only known fossil in the oldest strata of all, the Archæan, is the much-discussed *Eozoon canadense*, probably of animal origin; but the occurrence here of large deposits of graphite seems to indicate the existence of a considerable flora which has, unfortunately, become quite undeterminable. Thus, whilst there is some evidence that the primitive plants were Algæ, there is at present no available record of the various stages through which the Silurian and Devonian vascular plants were evolved from them.

### *Morphology.*

If inquiry be made as to the cause of the great advance in the recognition of the true affinities of plants, and consequently in their classification, which distinguishes the nineteenth century, I would refer it to the progress made in the study of morphology. The earlier botanists regarded all the various parts of plants as "organs" in relation to their supposed function; hence their description of plants was simply "organography." The idea of regarding the parts of the plant-body, not in connection with their functions, but with reference to their development and their mutual relations, seems to have originated with Jung in the seventeenth century (1687): it was revived by C. F. Wolff about seventy years later (1759), but it did not materially affect the study of plants until well on in the nineteenth century, after Goethe had repeatedly written on the subject and had devised the term "morphology" to designate it. For a time this somewhat abstract mode of treatment led to mere theorising and speculation, so much so that the years 1820–1840 will always be stigmatised as the period of the "Naturphilosophie." But fortunately this time of barrenness was succeeded by a veritable renascence. Robert Brown and Henfrey in England; Brongniart, St. Hilaire and Tulasne in France; Mohl, Schleiden, Naegeli, A. Braun, and, above all, Hofmeister in Germany, led the way back from the pursuit of fantastic will-o'-the-wisps to the observation of actual fact. Instead of evolving schemes out of their own internal consciousness as to how plants ought to be constructed, they endeavoured to discover by the study of development, and more particularly of embryogeny, how they actually are constructed, with the result that within a decade Hofmeister discovered the alternation of generations in the higher plants; a discovery which must ever rank as one of the most brilliant triumphs of morphological research.

With the knowledge thus acquired it became possible to determine the true relations of the various parts of the plant-body; to distinguish these parts as "members" rather than as "organs"; in a word, to establish homologies where hitherto only analogies had been traced—which is the essential difference between morphology and organography.

The publication of the "Origin of Species" profoundly affected the progress or morphology, as of all branches of biological research: but it did not alter its trend; it confirmed and extended it. We are not satisfied now with establishing homologies, but we go on to inquire into the origin and phylogeny of the members of the body. In illustration I may briefly refer to two problems of this kind which at the present time are agitating the botanical world. The first is as to the origin of the alternation of generations. Did it come about by the modification of the sexual generation (gametophyte) into an asexual (sporophyte); or is the sporophyte a new formation intercalated into the life-history? In a word, is the alternation of generations to be regarded as homologous or as antithetic? I am not rash enough to express any opinion on this controversy; nor is it necessary that I should do so, since the subject has twice been threshed out at recent meetings of this Section. The second problem is as to the origin of the sphorophylls, and, indeed, of all the various kinds of leaves of the sporophyte in the higher plants. It is suggested, on the one hand, that the sporophylls of the Pteridophyta have arisen by gradual sterilisation and segmentation from an unsegmented and almost wholly reproductive body, represented in our day by the sporogonium of the Bryophyta; and that the vegetative leaves have been derived by further sterilisation from the sporophylls. On the other hand, it is urged that the vegetative leaves are the more primitive, and that the sporophylls have been derived from them. It will be at once observed that this second problem is intimately connected with the first. The sterilisation theory of the origin of leaves is a necessary consequence of the antithetic view of the alternation of generations; whilst the derivation of sporophylls from foliage-leaves is similarly associated with the homologous view. Here, again, exercising a wise discretion, I will only venture to express my appreciation of the important work which has been done in connection with this controversy—work that will be equally valuable, whatever the issue may eventually be.

I will conclude my remarks on morphology with a few illustrations of the aid which the advance in this department has given to the progress of classification. For instance, Linnæus divided plants into Phanerogams and Cryptogams, on the ground that in the former the reproductive organs and processes are conspicuous, whereas in the latter they are obscure. In view of our increased knowledge of Cryptogams this ground of distinction is no longer tenable; whilst still recognising the validity of the division, our reasons for doing so are altogether different. For us, Phanerogams are plants which produce a seed; Cryptogams are plants which do not produce a seed. Again, we distinguish the Pteridophyta and the Bryophyta from the Thallophyta, not on account of their more complex structure, but mainly on the ground that the alternation of generations is regular in the two former groups, whilst it is irregular or altogether wanting in the latter. Similarly, the essential distinction between the Pteridophyta and the Bryophyta is that in the former the sporophyte, in the latter the gametophyte, is the preponderating form. It has enabled us further to correct in many respects the classifications of our predecessors by altering the systematic position of various genera, and sometimes of larger groups. Thus the Cycadaceæ have been removed from among the Monocotyledons, and the Coniferæ from among the Dicotyledons, where de Candolle placed them, and have been united with the Gnetaceæ into the sub-class Gymnospermæ. The investigation of the development of the flower, in which Payer led the way, and the elaboration of the floral diagram which we owe to Eichler, have done much, though by no means all, to determine the affinities of doubtful Angiosperms, especially among those previously relegated to the lumber-room of the Apetalæ.

### *Anatomy and Histology.*

Passing now to the consideration of the progress of knowledge concerning the structure of plants, the most important result to be chronicled is the discovery that the plant-body consists of living substance indistinguishable from that of which the body of animals is composed. The earlier anatomists, whilst recognising the cellular structure of plants, had confined their attention to the examination of the cell-walls, and described the contents as a watery or mucilaginous sap, without determining where or what was the seat of life. In 1831 Robert Brown discovered the nucleus of the cell, but there is no evidence that he regarded it as living. It was not until the renascence of research in the 'forties, to which I have already alluded, that any real progress in this direction was made. The cell-contents were especially studied by Naegeli and by Mohl, both of whom recognised the existence of a viscous substance lining the wall of all living cells as a "mucous layer" or "primordial utricle," but differing chemically from the substance of the wall by being nitrogenous: this they regarded as the living part of the cell, and to it Mohl (1846) gave the name "protoplasm," which it still bears. The full significance of this discovery became apparent in a somewhat roundabout way. Dujardin, in 1835, had described a number of lowly organisms, which he termed Infusoria, as consisting of a living substance, which he called "sarcode." Fifteen years later, in a remarkable paper on *Protococcus pluvialis*, Cohn drew attention to the similarity in properties between the "sarcode" of the Infusoria and the living substance of this plant, and arrived at the brilliant generalisation that the "protoplasm" of the botanists and the "sarcode" of the zoologists are identical. Thus arose the great conception of the essential unity of life in all living things, which, thanks to the subsequent labours of such men as de Bary, Brücke, and Max Schultze, in the first instance, has become a fundamental canon of Biology.

A conspicuous monument of this period of activity is the cell-theory propounded by Schwann in 1839. Briefly stated, Schwann's theory was that all living bodies are built up of structural units which are the cells: each cell possesses an independent vitality, so that nutrition and growth are referable, not to the organism as a whole, but to the individual cells. This conception of the structure of plants was accepted for many years, but it has had to give way before the advance of anatomical knowledge. The recognition of cell-division as the process by which the cells are multiplied—in opposition to the Schleidenian theory of free cell-formation—early suggested doubts as to the propriety of regarding the body as being built up of cells as a wall is built of bricks. Later the minute study of the Thallophyta revealed the existence of a number of plants, such as the Myxomycetes, the phycomycetous Fungi, and the siphonaceous Algæ, some of them highly organised, the vegetative body of which does not consist of cells. It became clear that cellular structure is not essential to life; that it may be altogether absent or present in various degree. Thus in the higher plants the protoplasm is segmented or septated by walls into uninucleate units or "energids" (Sachs), and such plants are well described as "completely septate." But in others, such as the higher Fungi and certain Algæ (e.g. *Cladophora*, *Hydrodictyon*), the protoplasm is septated, not into energids, but into groups of energids, so that the body is "incompletely septate." Finally there are the Thallophyta already enumerated, in which there is complete continuity of the protoplasm: these are "unseptate." Moreover, even when the body presents the most complete cellular structure, the energids are not isolated, but are connected by delicate protoplasmic fibrils traversing the intervening walls; a fact which is one of the most striking discoveries in the department of histology. This was first recognised in the sieve-tubes by Hartig (1837); then by Naegeli (1846) in the tissues of the Florideæ. After a long period of neglect the matter was taken up once more by Tangl (1880), when it attracted the attention of many investigators, as the result of whose labours, especially those of Mr. Gardiner, the general and perhaps universal continuity of the protoplasm in cellular plants has been established. Hence the body is no longer regarded as an aggregate of cells, but as a more or less septated mass of protoplasm: the synthetic standpoint of Schwann has been replaced by one as distinctively analytic.

Time does not permit me to do more than mention the important discoveries made of late years, mainly on the initiative of Strasburger, with regard to the details of cytology, and especially to the structure of the nucleus and the intricate dance of the chromosomes in karyokinesis. Indeed, I can do but scant justice to those anatomical discoveries which are of more exclusively botanical interest. One important generalisation which may be drawn is that the histological differentiation of the plant proceeds, not in the protoplasm, as in the animal, but in the cell-wall. It is remarkable, on the one hand, how similar the protoplasm is, not only in different parts of the same body, but in plants of widely different affinities; and, on the other, what diversity the cell-wall offers in thickness, chemical composition, and physical properties. In studying the differentiation of the cell-wall the botanist has received valuable aid from the chemist. Research in this direction may, in fact, be said to have begun with Payen's fundamental discovery (1844) that the characteristic and primary chemical constituents of the cell-wall is the carbohydrate which he termed cellulose.

The amount of detailed knowledge as to the anatomy of plants which has been accumulated during the century by countless workers, among whom Mohl, Naegeli, Unger and Sanio deserve special mention as pioneers, is very great—so great, indeed, that it seemed as if it must remain a mere mass of facts in the absence of any recognisable general principles which might serve to marshal the facts into a science. The first step towards a morphology of the tissues was Hanstein's investigation of the growing point of the Phanerogams (1868), and his recognition therein of the three embryonic tissue-systems. This has lately been further developed by the promulgation of van Tieghem's theory of the stele, which is merely the logical outcome of Hanstein's distinction of the plerome. It has thus become possible to determine the homologies of the tissue-systems in different plants and to organise the facts of structure into a scientific comparative anatomy. It has become apparent that, in many cases, differences of structure are immediately traceable to the influence of the environment; in fact, the study of physiological or adaptive anatomy is now a large and important branch of the subject.

The study of Anatomy has contributed in some degree to the progress of systematic Botany. It is true that some of the more ambitious attempts to base classification on Anatomy have not been successful; such, for instance, as de Candolle's subdivision of Phanerogams into Exogens and Endogens, or the subdivision of Cormophyta into Acrobrya, Amphibrya, and Acramphibrya, proposed by Unger and Endlicher. Still it cannot be denied that anatomical characters have been found useful, if not absolutely conclusive, in suggesting affinities, especially in the determination of fossil remains. A large proportion of our knowledge of extinct plants, to which I have already alluded, is based solely upon the anatomical structure of the vegetative organs; and although affinities inferred from such evidence cannot be regarded as final, they suffice for a provisional classification until they are confirmed or disproved by the discovery and investigation of the reproductive organs.

### *Physiology.*

The last branch of botanical science which I propose to pass in review is that of physiology. We may well begin with the nutritive processes. At the close of the eighteenth century there was practically no coherent theory of nutrition; such as it was it amounted to little more than the conclusion arrived at by van Helmont a century and a half earlier, that plants require only water for their food, and are able to form from it all the different constituents of their bodies. It is true that the important discovery had been made and pursued by Priestley (1772), Ingen-Housz (1780) and Sénébier (1782) that green plants exposed to light absorb carbon dioxide and evolve free oxygen; but this gaseous interchange had not been shown to be the expression of a nutritive process. At the opening of the nineteenth century (1804) this connection was established by de Saussure, in his classical "Recherches Chimiques," who demonstrated that, whilst absorbing carbon dioxide and evolving oxygen, green plants gain in dry weight; and he further contributed to the elucidation of the problem of nutrition by showing that, whilst assimilating carbon dioxide, green plants also assimilate the hydrogen and oxygen of water.

Three questions naturally arose in connection with de Saussure's statement of the case: What is the nature of the organic substance formed? What is the function of the chlorophyll? What is the part played by light? It was far on in the century before answers were forthcoming.

With regard to the first of these questions the researches of Boussingault (1864) and others established the fact that the volume of carbon dioxide absorbed and that of the oxygen evolved in connection with the process are approximately equal. Further, the frequent presence of starch in the chloroplastids, to which Mohl first drew attention (1837), was subsequently found by Sachs (1862) to be closely connected with the assimilation of carbon dioxide. The conclusion drawn from these facts is that the gain in dry weight accompanying the assimilation of carbon dioxide is due to the formation, in the first instance, of organic substance having the composition of a carbohydrate; a conclusion which may be expressed by the equation

$$CO_2 + H_2O = CH_2O + O_2.$$

The questions with regard to chlorophyll and to light are so intimately connected that they must be considered together. The first step towards their solution was the investigation of the relative activity of light of different colours, originally undertaken by Sénébier (1782) and subsequently repeated by Daubeny (1836), with the result that red and orange light was found to promote assimilation in a higher degree than blue or violet light. Shortly afterwards Draper (1843), experimenting with an actual solar spectrum, concluded that the most active rays are the orange and yellow; a conclusion which was generally accepted for many years. But in the meantime the properties of the green colouring matter of plants (to which Pelletier and Caventou gave the name "chlorophyll" in 1817) were being investigated. Brewster discovered in 1834 that an alcoholic extract of green leaves presents a characteristic absorption spectrum; but many years elapsed before any attempt was made to connect this property with the physiological activity of chlorophyll. It was not until 1871–72 that Lommel and N. J. C. Müller pointed out that the rays of the spectrum which are most completely absorbed by chlorophyll are just those which are most efficient in the assimilation of carbon dioxide. Subsequent researches, particularly those of Timiriazeff (1877), and those of Engelmann (1882–84) based on his ingenious Bacterium-method, have confirmed the views of Lommel and of Müller, and have placed it beyond doubt that the importance of light in the assimilatory process is that it is the form of kinetic energy necessary to effect the chemical changes, and that the function of chlorophyll is to serve as the means of absorbing this energy and of making it available for the plant.

These are perhaps the most striking discoveries in relation to the nutrition of plants, but there are others of not less importance to which brief allusion must be made. We owe to de Saussure (1804) the first clear demonstration of the fact that plants derive an important part of their food from the soil; but the relative nutritive value of the inorganic salts absorbed in solution was not ascertained until Sachs (1858) reintroduced the method of water-culture which had originated centuries before with Woodward (1699) and had been practised by Duhamel (1768) and de Saussure. Special interest centres around the question of the nitrogenous nutrition of plants. It was long held chiefly on the authority of Priestley and of Ingen-Housz, and in spite of the contrary opinion expressed by Sénébier, Woodhouse (1803) and de Saussure, that plants absorb the free nitrogen of the atmosphere by their leaves. This view was not finally abandoned until 1860, when the researches of Boussingault and of Lawes and Gilbert deprived it of all foundation. Since then we have learned that the free nitrogen of the air can be made available for nutrition—not indeed directly by green plants themselves, but, as Berthelot and Winogradsky more especially have shown, by Bacteria in the soil, or, as apparently in the Leguminosæ, by Bacteria actually enclosed in the roots of the plants with which they live symbiotically.

We now turn from the nutritive or anabolic processes to those which are catabolic. The discovery of the latter, just as of the former, was arrived at by the investigation of the gaseous interchange between the plant and the atmosphere. In the eighteenth century Scheele and Priestley had found that, under certain circumstances, plants deteriorate the quality of air; but it is to Ingen-Housz that we owe the discovery that plants, like animals, respire, taking in oxygen and giving off carbon dioxide. And when Sénébier (1800) had ascertained for the inflorescence of *Arum maculatum*, and later de Saussure (1822) for other flowers, that active respiration is associated with an evolution of heat, the connection between respiration and catabolism was established for plants as it had been long before by Lavoisier (1777) in the case of animals.

Among the catabolic processes which have been investigated none are of greater importance than those which are designated by the general term *fermentations*. The first of these to be discovered was the alcoholic fermentation of sugar. Towards the end of the seventeenth century Leeuwenhoek had detected minute globules in fermenting wort; and a century later Lavoisier had ascertained that the chemical process consists in the decomposition of sugar into alcohol and carbon dioxide; but it was not until 1837–38 that, almost simultaneously, Cagniard de Latour, Schwann and Kützing discovered that Leeuwenhoek's globules were living organisms, and were the cause of the fermentation. Shortly before, in 1833, Payen and Persoz extracted from malt a substance named *diastase*, which they found could convert the starch of the grain into sugar. These two classes of bodies, causing fermentative changes, were distinguished respectively as *organised* and *unorganised* ferments. The number of the former was rapidly added to by the investigation more especially of the Bacteria, in which Pasteur led the way. The extension of our knowledge of the unorganised ferments, or enzymes, has been even more remarkable; we now know that very many of the metabolic processes are effected by various enzymes, such as those which convert the more complex carbohydrates into others of simpler constitution (diastase, cytase, glucase, inulase, invertase); those which decompose glucosides (emulsin, myrosin, &c.); those which act on proteids (trypsins) and on fats (lipases); the oxidases, which cause the oxidation of various organic substances; and the zymase, recently extracted from yeast, which causes alcoholic fermentation.

The old distinction of the micro-organisms as "organised ferments" is no longer tenable; for, on the one hand, certain of the chemical changes which they effect can be traced to extractable enzymes which they produce; and, on the other, as Pasteur has asserted, every living cell may become an "organised ferment" under appropriate conditions. The distinction now to be drawn is between those processes which are due to enzymes and those directly effected by living protoplasm. Many now definitely included in the former class were, until lately, regarded as belonging to the latter; and no doubt future investigation will still further increase the number of the former at the expense of the latter.

The consideration of the metabolic processes leads naturally to that of the function of transpiration and of the means by which water and substances in solution are distributed in the plant. This is perhaps the department of physiology in which progress during the nineteenth century has been least marked. We have got rid, it is true, of the old idea of an ascending crude sap, and of a descending elaborated sap, but there have been no fundamental discoveries. With regard to transpiration itself, we know more of the detail of the process, but that is all that can be said. As for root-pressure, Hofmeister (1858–82) discovered that "bleeding"—as the phenomena of root-pressure were termed by the earlier writers—is not confined, as had hitherto been thought, to trees and shrubs; but the current theory of the process, allowing for the discovery of protoplasm and of osmosis, has advanced but little upon that given by Grew in the third book of his "Anatomy of Plants" (1675). Again, the mechanism of the transpiration-current in lofty trees remains an unsolved problem. To begin with, there is still some doubt as to the exact channel in which the current travels. Knight (1801–8) first proved that the current travels in the alburnum of the trunk, but not, he thought, in the vessels, for he found them to be dry in the summer, when transpiration is most active; a view in which Dutrochet (1837) subsequently concurred. Meyen (1838) then suggested that the water must travel, not in the lumina, but in the substance of the cells of the vessels, and was supported by such eminent physiologists as Hofmeister (1858), Unger (1864, 1868) and Sachs (1878); but it has since been strongly asserted by Boehm, Elfving, Vesque, Hartig and Strasburger that the young vessels always contain water, and that the current travels in the lumina and not in the walls of the vessels.

Now as to the force by which the water of the transpiration-current is raised from the roots to the topmost leaf of a lofty tree. From the point of view that the water travels in the substance of the walls the necessary force need not be great, and would be amply provided by the transpiration of the leaves, inasmuch as the weight of the water raised would be supported by the force of imbibition of the walls. From the point of view that the water travels in the lumina, the force required to raise and support such long columns of water must be considerable. Dismissing at once as quite inadequate such purely physical theories as those of capillarity and gas-pressure, there remain two theories as to the nature of this force which resemble each other in being essentially vitalistic, but differ in that the one involves pressure from below, the other suction from above. In the one, suggested by Godlewski and by Westermaier (1884), the cells of the medullary rays and of the wood-parenchyma are supposed to absorb liquid from the vascular tissue at one level and force it back again by a vital act at a higher level: this theory was disposed of by the fact that the transpiration-current can be maintained through a considerable length of a stem killed by heat or by poison. In the other, suggested by Dixon and Joly (1895–99), and also by Askenasy (1895–96), it is assumed that there are, in the trunk of a transpiring tree, continuous columns of water which are in a state of tensile stress, the tension being set up by the vital transpiratory activity of the leaves. Some idea of the enormous tension thus assumed is given by the following simple calculation relating to a tree 120 feet high. Not only has the liquid to be raised to this height, but in its passage upwards a resistance calculated to be equal to about five times the height of the tree has to be overcome. Hence the transpiration-force in such a tree must at least equal the weight of a column of water 720 feet in height; that is, a pressure of about twenty-four atmospheres, or 360 lb. to the square inch. But there is no evidence to prove that a tension of anything like twenty atmospheres exists, as a matter of fact, in a transpiring tree; on the contrary, such observations as exist (*e.g.* those of Hales and of Boehm) indicate much lower tensions. Under these circumstances we must regretfully confess that yet one more century has closed without bringing the solution of the secular problem of the ascent of the sap.

The nineteenth century has been, fortunately, rather more fertile in discovery concerning the movements and irritability of plants. But it is surprising how much knowledge on these points had been accumulated by the beginning of the century: the facts of plant-movement, such as the curvatures due to the action of light, the sleep-movements of leaves and flowers, the contact-movements of the leaves of the sensitives, were all familiar. The nineteenth century opened, then, with a considerable store of facts; but what was lacking was an interpretation of them; and whilst it has largely added to the store, its most important work has been done in the direction of explanation.

The first event of importance was the discovery by Knight, in 1806, of the fact that the stems and roots of plants are irritable to the action of gravity and respond to it by assuming definite directions of growth. Many years later the term "geotropism" was introduced by Frank (1868) to designate the phenomena of growth as affected by gravity, and at the same time Frank announced the important discovery that dorsiventral members, such as leaves, behave quite differently from radial members, such as stems and roots, in that they are diageotropic.

It was a long time before the irritability of plants to the action of light was recognised. Chiefly on the authority of de Candolle (to whom we owe the term "heliotropism"), heliotropic curvature was accounted for by assuming that the one side received less light than the other, and therefore grew the more rapidly. But the researches of Sachs (1873) and Müller-Thurgau (1876) have made it clear that the direction of the incident rays is the important point, and that a radial stem, obliquely illuminated, is stimulated to curve until its long axis coincides with the incident rays. Moreover, the discovery by Knight (1812) of negative heliotropism in the tendrils of *Vitis* and *Ampelopsis* really put the Candollean theory quite out of court; and further evidence that heliotropic movements are a response to the stimulus of the incident rays of light is afforded by Frank's discovery of the diaheliotropism of dorsiventral members.

The question of the localisation of irritability has received a good deal of attention. The fact that the under surface of the pulvinus of *Mimosa pudica* is alone sensitive to contact was ascertained by Burnett and Mayo in 1827; and shortly after (1834) Curtis discovered the sensitiveness of the hairs on the upper surface of the leaf of *Dionaea*. After a long period of neglect the subject was taken up by Darwin. The irritability of tendrils to contact had been discovered by Mohl in 1827; but it was Darwin who ascertained, in 1865, that it is confined to the concavity near the tip. In 1875 Darwin found that the irritability of the tentacles of *Drosera* is localised in the terminal gland; and followed this up, in 1880, by asserting that the sensitiveness of the root is localised in the tip, which acts like a brain. This assertion led to a great deal of controversy, but the researches of Pfeffer and Czapek (1894) have finally established the correctness of Darwin's conclusion. It is interesting to recall that Erasmus Darwin had suggested the possible existence of a brain in plants in his "Phytologia" (1800). But the word "brain" is misleading, inasmuch as it might imply sensation and consciousness: it would be more accurate to speak of centres of ganglionic activity. However, the fact remains that there exist in plants irritable centres which not only receive stimuli but transmit impulses to those parts by which the consequent movement is effected. The transmission of stimuli has been found in the case of *Mimosa pudica* to be due to the propagation of a disturbance of hydrostatic equilibrium along a special tissue; in other cases, where the distance to be traversed is small, it is probably effected by means of that continuity of the protoplasm to which I have already alluded.

Finally, as regards the mechanism of these movements, we find Sénébier and Rudolphi, the earliest writers on the subject in the nineteenth century, asserting, as if against some accepted view, that there is no structure in a plant comparable with the muscle of an animal. Rudolphi (1807) suggested, as an alternative, that the position of a mobile leaf is determined by the "turgor vitalis" of the pulvinus, and thus anticipated the modern theory of the mechanism. But he gives no explanation of what he means by "turgor"; and the term is frequently used by writers in the first half of the century in the same vague way. Some progress was made in consequence of the discovery of osmosis by Dutrochet (1828), and more especially by his observation (1837) that the movements of *Mimosa* are dependent on the presence of oxygen, and are therefore vital. But it was not, and could not be, until the existence of living protoplasm in the cells of plants was realised, and the movements of free-swimming organisms and naked reproductive cells had become more familiar, that the true nature of the mechanism began to be understood; and then we find Cohn saying, as long ago as 1860, that "the living protoplasmic substance is the essentially contractile portion of the cell." This statement may, perhaps, seem to put the case too bluntly, and to savour too much of animal analogy; but the study of the conditions of turgidity has shown more and more clearly that the protoplasm is the predominant factor. The protoplasm of plant-cells is undoubtedly capable of rapid molecular changes, which alter its physical properties, more particularly its permeability to the cell-sap. It may be that these changes cannot be directly compared with those going on in animal muscle; but if we use the term "contractility" in its wider sense, as indicating a general property of which muscular contraction is a special case, then Cohn's statement is fully justified. This is borne out by the observations of Sir J. Burdon-Sanderson (1882–88) on the electrical changes taking place in the stimulated leaf of *Dionaea*, and by Kunkel's (1878) corresponding observations on *Mimosa pudica*: in both cases the electrical changes were found to be essentially the same as those observable on the stimulation of muscle. We find, then, that the advances in Physiology, like those in Anatomy, teach the essential unity of life in all living things, whether we call them animals or plants.

With this in our minds we may go on to consider in conclusion, and very briefly, that department of physiological study which is known as the Bionomics of Œcology of plants. In the earlier part of the century this subject was studied more especially with regard to the distribution of plants, and their relation to soil and climate; but since the publication of the "Origin of Species" the purview has been greatly extended. It then became necessary to study the relation of plants, not only to inorganic conditions, but to each other and to animals; in a word, to study all the adaptations of the plant with reference to the struggle for existence. The result has been the accumulation of a vast amount of most interesting information. For instance, we are now fairly well acquainted with the adaptations of water-plants (hydrophytes) on the one hand, and of desert-plants (xerophytes) on the other; with the adaptations of shade-plants and of those growing in full sun, especially as regards the protection of the chlorophyll. We have learned a great deal as to the relations of plants to each other, such as the peculiarities of parasites, epiphytes and climbing plants, and as to those singular symbioses (Mycorhiza) of the higher plants with Fungi which have been found to be characteristic of saprophytes. Then, again, as to the relations between plants and animals: the adaptation of flowers to attract the visits of insects, first discovered by Sprengel (1793), has been widely studied; the protection of the plant against the attacks of animals, by means of thorns and spines on the surface, as also by the formation in its tissues of poisonous or distasteful substances, and even by the hiring of an army of mercenaries in the form of ants, has been elucidated; and finally those cases in which the plant turns the tables upon the animal, and captures and digests him, are now fully understood.

### *Conclusion.*

Imperfect as is the sketch which I have now completed, it will, I think, suffice to show how remarkable has been the progress of the science during the nineteenth century, more particularly the latter part of it, and how multifarious are the directions in which it has developed. In fact Botany can no longer be regarded as a single science; it has grown and branched into a congeries of sciences. And as we botanists regard with complacency the flourishing condition of the science whose servants we are, let us not forget, on the one hand, to do honour to those whose life work it was to make the way straight for us, and whose conquests have become our peaceful possession; nor, on the other, that it lies with us so to carry on the good work that when this Section meets a hundred years hence it may be found that the achievements of the twentieth century do not lag behind those of the nineteenth.

---

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

As was explained at length in our issue of March 22, in accordance with the new statutes of the University of London, a reconstituted Senate is to be elected shortly. The new Senate will be composed of the Chancellor, the Chairman of Convocation and fifty-four Senators, of whom sixteen are to be elected by Convocation. These sixteen members of the Senate will have, it would appear from the statutes, two distinct functions. They will, in addition to their general duties as senators, be required to form a special council for external students. This council, which is to consist of twenty-eight members of the Senate, will include the chancellor, the vice-chancellor, the chairman of Convocation, the sixteen senators elected by Convocation, and nine other members of the Senate elected by the Senate. Members of Convocation will, in a few days, proceed to choose their sixteen representatives; and, not unnaturally, there is considerable diversity of opinion as to the suitability of the nominated candidates. Two rival associations have sprung up. One body of graduates insists that the duties to be performed upon the council for external students should be considered of paramount importance in electing senators; the other, that their responsibilities as members of the Senate should be kept continually in view, because the work of the new University as a whole, but more especially the development of its teaching facilities, is of the most pressing nature. While admitting the necessity of safe-guarding the interests of the external student, and of ensuring the high value of the degrees of the University, it is desirable that every possible means of improving the higher education of London should receive primary consideration. It would be nothing less than a calamity were Convocation to elect sixteen irreconcilables with no ideas outside that of introducing the peculiar, though somewhat circumscribed, needs of the external student into all deliberations of the Senate. It is therefore to be hoped that the common-sense which attended the election of their representative in Parliament will characterise the selection of the sixteen senators chosen by Convocation. It is easily possible to find members of the University who, while fully aware of the needs, and in sympathy with the aims of the external student, have also broad views as to the work of a great teaching University.

DR. A. P. LAURIE, lecturer in physics and chemistry at St. Mary's Hospital Medical School, has been appointed principal of the Heriot Watt College, Edinburgh.

DR. SPENCER W. RICHARDSON, lecturer on physics at the University College, Nottingham, has been appointed principal and professor of physics at the Hartley College, Southampton.

THE Birkbeck Institution, London, which has now completed seventy-seven years of educational work in the metropolis, commences its new session on Monday, October 1. The Institution has had many additions to its appliances in recent years, and the physical, chemical and metallurgical laboratories are now very thoroughly equipped. The day classes provide courses in chemistry, biology, physics and mathematics for the science degrees of London University. During the recess considerable additions and improvements have been made by the aid of a gift of 2000 guineas from Mr. F. Ravenscroft, to commemorate his completion of a membership of fifty years.

ADDRESSES will be given at the opening of many of the metropolitan and provincial medical schools at the beginning of October. At Middlesex Hospital on October 1, Dr. T. Clifford Allbutt, F.R.S., will distribute the prizes gained during the previous year and deliver an address. At St. George's Hospital the introductory address will be delivered by Dr. Francis G. Penrose. At University College the session of the faculty of medicine will be opened by Prof. G. Vivian Poore; the session of the faculty of arts and laws, and of science, will be opened with an address by Prof. F. W. Oliver on October 2. At St. Mary's Hospital the introductory address will be given by Mr. H. S. Collier. At St. Thomas's Hospital the session will open on Tuesday, October 2, when the prizes will be distributed by Sir William MacCormac. At the opening of the session at Charing Cross Hospital on October 2, Lord Lister will deliver the third biennial Huxley Lecture. The London School of Tropical Medicine will open on October 1, and the introductory address will be delivered by Sir William MacGregor, K.C.M.G., C.B., on Wednesday, October 3. At the London School of Medicine for Women the introductory address will be given on October 1 by Miss Aldrich Blake, M.S., M.D., after which the prizes for the past year will be distributed, At the Royal Veterinary College the introductory address will be delivered by Prof. McFadyean. The winter session at the University of Birmingham will begin on October 1 with an address by Prof. B. C. A. Windle. At University College of South Wales and Monmouthshire, Cardiff, the address will be delivered on October 1 by Sir John Williams. At University College, Liverpool, the Bishop of Liverpool will deliver an address on October 13 and distribute the prizes.

A SUMMARY of the scheme of work carried on by the Essex Technical Instruction Committee for the promotion of interest in the science of agriculture and other branches of knowledge bearing upon rural industries, has been prepared by Messrs. T. S. Dymond and J. H. Nicholas. The work is in every respect satisfactory, and should do much to broaden the views of the practical farmers of the county as to the value of agricultural education and experiment. Every year an educational excursion extending over several days is organised, the one this year being to Denmark to study dairy farms and dairying, high school and agricultural education, co-operation and organisation of agricultural industry there. Field experiments are carried out by arrangement with farmers distributed in all parts of the county, the advantage being that as demonstrations of the effect of manures, &c., they receive wider attention, and also that the experiments can be made on each of the different classes of land occurring in the county. Meetings of farmers are held in the experimental fields in each district at the season most suitable for studying the results of the experiments. The County Technical Laboratories at Chelmsford are now recognised as a centre from which information upon agricultural matters can be obtained. The advice of the staff is frequently sought on insect and fungoid pests, on difficulties met with in the dairy, &c., and their opinion asked on the value of foods and of fertilisers, and the best manurial treatment of land. As occasion arises, inquiries are undertaken on matters of agricultural importance, such as the chemical and physical effect of the salt water inundation upon agricultural land on the coast of Essex, and the best method for its amelioration. The agricultural work of the Essex Technical Instruction Committee is thus of the same character as that carried on by the Government

Agricultural Experiment Stations in the United States and elsewhere.

THIS is the time of year when prospectuses and calendars of Technical Colleges, Schools, and Institutes are received from various parts of the country in such numbers that it is impossible to do justice to them in a short note. Several publications of this character recently received must, however, be mentioned. The Northampton Institute, Clerkenwell, the principal of which is Dr. R. M. Walmsley, has greatly developed, and has commenced a set of day courses in mechanical engineering, electrical engineering and horological engineering. These courses have already been announced in NATURE, and their scope described. Other changes tending to the greater efficiency of the Institute have been introduced. A noteworthy point is that in many parts of the prospectus notes are given which should be of real value in making students understand what true education means, and in directing their energies in proper channels. The notes are in complete accord with rational methods of instruction.

THE Merchant Venturers' Technical College at Bristol has for many years heen prominent among the the technical schools of the country. It aims at providing a sound, continuous, and complete preparation for an industrial career, and has developed with the times. Among recent improvements mentioned in the calendar we notice that a much larger physical laboratory has been equipped and will be opened this session, and also an additional special laboratory for heat and mechanical physics.

THE prospectus of the Municipal Science, Art and Technical Schools of Devonport has been received. Remembering the tendency of students to skim over many subjects, instead of concentrating their attention on a few, we are glad to see among the regulations of the school the following note:—"Students are strongly advised not to attempt more than three subjects, one of which should be practical geometry or mathematics, and they should consult the teacher as to the course of study most suitable to their profession."

THE Municipal Technical School of Manchester is one of the finest in the country, and its syllabus for the session 1900–1901 is proportionally attractive. The following extract from the syllabus shows the relation of the work of the school to that of a University College. "The chief object of the school is to provide instruction in the principles of those sciences which bear directly or indirectly upon our trades and industries, and to show by experiment how these principles may be applied to their advancement. The aim of the school is distinct from that of the University Colleges, inasmuch as it is designed to teach science solely with a view to its industrial and commercial applications, and not for the purpose of educating professional scientific men. It, however, offers to students of the University Colleges the opportunity of technical instruction in the industrial applications of certain branches of science."

THE Calendar of the Royal Technical Institute, Salford, contains much good advice to students, and many sound remarks upon objects and methods of study. In the day classes of the Institute, the number of hours per week allotted to each subject in the first year is as follows:—mathematics 6; general physics (including mechanics) 4; practical physics 3; electricity (theoretical) 2; electricity (practical) 2; theoretical chemistry 2; practical chemistry 3; practical, plane and solid geometry 2½; drawing (freehand, model, &c.) 3; workshop practice 2; English and French 4; total 33½. The second and third years' courses become more specialised according to the department which the student proposes to enter. There is no compulsory course of instruction for evening students. Students are free to select those classes which will help them to make progress in their particular trade or business. They are warned, however, against strictly confining themselves to such classes; it is pointed out that if they desire to gain a thoroughly sound knowledge in technical subjects, the study of them should be preceded by several of the pure and applied sciences. Thus, for example, little real progress can be made in applied mechanics without a knowledge of theoretical mechanics: or in machine or building construction without geometry; and unless the student undergoes systematic instruction in mensuration, arithmetic and mathematics, he will derive very little benefit from such subjects as steam, machine design, physics, &c. Mathematics has been aptly termed the alphabet of science, and students should not fail to acquire mathematical knowledge if they wish to make satisfactory progress in science and technology. The work of an Institute inspired with this spirit cannot fail to be of value.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, September 17.—M. Maurice Lévy in the chair.—Remarks relating to the decomposition of nitric esters and of nitroglycerine by alkalis, and on the relative stability of explosive materials, by M. Berthelot. In certain cases, instead of the production of the alcohol and nitrate as in the normal reaction, an aldehyde is formed, together with some nitrite. The results of M. Leo Vignon upon the nitrocelluloses confirm these views.—On the nomographic resolution of the equation of the seventh degree, by M. Maurice d'Ocagne.—On the deformations of contact of elastic bodies, by M. A. Lafay. Spheres of bronze and steel were studied and the amount of compression under varying loads measured by optical arrangements analogous to the Fizeau apparatus for the measurement of the expansion of crystals. The application of the theory developed by Hertz showed differences between the calculated and observed values which increased with the radius of the sphere. Since this divergence might possibly be due to the mutual friction of the surfaces in contact, experiments were made with oiled spheres, but the results were not affected by the lubrication.—Action of iodine and yellow oxide of mercury upon styrolene and safrol, by M. J. Bougault. Styrolene with iodine and mercuric oxide yielded an addition product, not obtainable pure, but apparently $C_6H_5\cdot CHI\cdot CH_2\cdot OH$, from which phenylacetic aldehyde was obtained by the action of silver nitrate. Safrol gives a similar addition product, but no aldehyde could be obtained from this by the action of silver nitrate.—On the reduction of the nitrocelluloses, by M. Leo Vignon. It has been shown in a previous paper that the nitration of cellulose yields, not nitrocelluloses, but nitro-oxycellulose containing an aldehyde group. With ferrous chloride, these bodies are reduced, the nitro-group being eliminated but the aldehyde group left intact. With ammonium sulphide, the reduction takes place in a different manner, cellulose or hydrocellulose being produced, substances without reducing action.

THURSDAY, OCTOBER 4, 1900.

## A MANUAL OF THE ECHINODERMS.

*A Treatise on Zoology.* Edited by E. Ray Lankester, F.R.S. Part iii. The Echinoderma. By F. A. Bather, J. W. Gregory and E. S. Goodrich. Pp. ix + 344. (London: A. and C. Black, 1900.)

THE first instalment of the long-expected "Oxford Zoology"—first, that is to say, in order of publication—will be heartily welcomed as filling a distinct gap in zoological literature, and not of this country alone. During the latter half of the nineteenth century scientific literature has accumulated with such rapidity as to render it practically impossible for a zoologist at the present day to master thoroughly more than a limited part of his subject. To acquire a knowledge of the results gained in fields other than that which he has made his speciality, he must be dependent to a large extent upon the manuals and guide-books compiled by those who are sufficiently familiar with the latest discoveries in particular branches of zoology to be able to give a clear and critical account of the present state of knowledge in these departments. Nowhere is this necessity more strongly felt than in dealing with the Echinoderms, a group in which the student is confronted, on the one hand, with intricate morphological problems and with phylogenetic questions of a most puzzling kind; and, on the other hand, with such a vast array of extinct types that the non-expert feels at once out of his depth when attempting to obtain an adequate knowledge of them. In the Pelmatozoa, practically half the phylum, we find a group of the greatest historical and phylogenetic importance, but one in which the existing forms teach us no more about the race in the past, and regarded as a whole, than do the modern Egyptians about the former dynasties whose remains are entombed in their land. The abundance of forms unearthed by the palæontologist has called forth a literature which exemplifies fully the danger of something like a deadlock in zoological science, as the result simply of its fertility. The student soon loses his way and finds himself struggling with a mass of hard facts and contradictory hypotheses, due on the one hand to the great diversity of form and structure in the objects themselves, and on the other hand to difficulties inseparable from the study of animals known almost entirely as fossils. Any one who has endeavoured, for instance, to gain an acquaintance with the structure and evolution of fossil Crinoids from the voluminous works of Messrs. Wachsmuth and Springer and other writers must have felt the urgent need for a guide and interpreter, failing whom it was necessary either to study deeply or to pass lightly by, to become an expert or to be content with ignorance. Yet no one with even a superficial acquaintance with the problems of Echinoderm morphology and phylogeny would willingly pass over the extinct forms, and least of all the more ancient Pelmatozoa, such as the Cystids and their allies, since it is obvious that here, if anywhere, is to be found in a concrete form the solution of many puzzles in the evolution of the phylum. Nowhere is palæontology, as a source of material evidence for theories of phylogeny, given so fair a trial as in the case of Echinoderms with their complete skeleton and consequent abundance of well-preserved fossil types, and it must be conceded that palæontology, if it condescends to speak clearly, can give the only final judgment in questions of evolution and ancestral history.

For many reasons, therefore, a plain and intelligible account of the Echinoderms, and especially of the Pelmatozoa, by those who have an expert knowledge of them, both as fossils and as recent forms, was greatly to be desired, and in the present volume we have the first complete treatise that has been published under these conditions in any language. The intention of the authors is to give a systematic account of the Echinoderms, including every known genus, living or extinct, and at the same time to trace as far as possible the evolution and relationships of the forms comprised under each class or order, as inferred both from their structural affinities and from their succession in time. The aim in view is therefore to effect a happy combination of the older styles of systematic treatise with the modern methods of comparative morphology, developmental history and phylogenetic speculation.

An introductory chapter, giving a general description of the organisation and development of Echinoderms, from the pen of Mr. Bather, attempts to trace the origin of the characteristic radiate symmetry from the bilateral ancestor represented by the Dipleurula larva. Like most other recent authorities on the group, Mr. Bather supports the opinion that the radiate symmetry was acquired in all Echinoderms during an ancestral fixed stage, in which the animal fed by means of currents produced by cilia and directed along special food-grooves towards the mouth. In all animals with this mode of nutrition, which was probably the primitive method in each of the principal phyla, except perhaps the Cnidaria and the Arthropods, the general tendency of evolution is towards a reduction or loss of active locomotion, and frequently towards fixation, which certainly occurred in the Echinoderms. The common ancestor of the phylum was, in fact, to all intents and purposes, a Pelmatozoon, fixed by the aboral pole, the original right side of the bilateral ancestor, and with ciliated grooves converging to the mouth on the upper side. Amongst the Cystids ancestral stages are to be found showing the gradual acquisition of a radiate pentamerous symmetry, first by the food-grooves and then by the skeleton and other organs of the body, last of all by the gonads. The Pelmatozoa retained permanently this mode of life, continually adapting and perfecting their organisation to the necessities entailed by it. The other Echinoderm classes, on the other hand, grouped together as Eleutherozoa, and including the modern starfishes, sea-urchins and holothurians must have become free again at a very early period after the acquisition of radiate symmetry, giving up their method of nutrition by means of ciliary currents, and losing in consequence their food-grooves, which atrophy as such, the condensation of the nerve-plexus at the base of the grooves persisting, and being further specialised as the "superficial" nervous system. The holothurians were the first stock to become Eleutherozoic, radiate symmetry in their case not having extended to the gonads, as it has in the case of the starfish and urchins.

The direct and positive evidence which is available may seem at first sight an insufficient foundation for the hypothesis of a Pelmatozoic ancestor of all Echinoderms, that is to say, a pre-Cambrian form in which the food-grooves initiated a radiate symmetry with which all other systems of organs gradually fell into line. But the necessity of some such assumption becomes irresistible when we realise by careful reflection the inadequacy of any other theory to account for the evolution of the characteristic radiate symmetry and the complete hold it has taken upon all organs of the echinoderm body. In the ontogeny of existing types it always seems as if it were the hydrocœle or water vascular system which actually set the tune to which all the other systems of organs dance, but it is difficult, if not impossible, to imagine clearly a course of ancestral evolution, limited and guided, as it must have been, by the necessities of the struggle for existence, in which the hydrocœle took the initiative in this respect, and did not itself follow the lead of some other system. The hydrocœle of the Pelmatozoic ancestor was probably at its first origin simply a compartment of the cœlom which had the function of furnishing tactile tentacles, formed as hollow outgrowths of the body-wall, in connection with the food-grooves. On this hypothesis it is easy to understand why the hydrocœle was the first system of organs to be affected by the radiate symmetry initiated by the primitive nutritive system, and consequently why, in the Eleutherozoa, after atrophy of the food-grooves, the symmetry should apparently start from the hydrocœle itself.

In the present volume the Pelmatozoa are also undertaken by Mr. Bather, who recognises four classes—Cystids, Blastoids, Crinoids and Edrioasterids. Another and perhaps more natural (*i.e.* phylogenetic) classification is hinted at (p. 39), but the arrangement quoted above is adopted as involving the least disturbance of established names and ideas. The Pelmatozoa occupy about two-thirds of the volume, and the treatment of this most difficult group cannot be too highly praised. An expert in this branch of zoology might perhaps find details to criticise or ideas with which to disagree; the worker in other fields can only express his appreciation of the erudition displayed and the labour expended in setting forth the structure and evolution of this vast series of forms. In a group which is to a large extent represented by fossils, and in which so little material is available at the present day for the scalpel and the microtome, it is natural that less space and attention should be given to the anatomy and morphology of the soft tissues than to that of the skeleton and its never-ending complications of plates and ossicles. A simple Crinoid is taken as a type of Pelmatozoic organisation, and its anatomy is briefly described. One small point, at least, in this description is open to criticism. The author identifies Ludwig's blood-vessel and ring in the Crinoid as the "pseudhæmal," *i.e.* perihæmal, system (pp. 100 and 102). This seems to be an oversight, as elsewhere (p. 26) he states that this system "is so much reduced in Crinoidea that its existence is denied by some authors." Since the perihæmal system of canals, where well developed, as in the starfish, has been shown very clearly to be of cœlomic origin, it is impossible to identify with it the Crinoid "blood-vessel," which has all the characters of the canals termed in this work the "lacunar" or "hæmal" system. If anything in the Crinoid arm is to be identified as perihæmal (a term we much prefer to pseudhæmal), then probably the subtentacular canals have the most right to this title, as being cœlomic canals which occupy approximately the same position as the perihæmal canals in the starfish, and which have also the same relation to the lateral nerve cords that the perihæmal canals have to "Lange's nerves." On this view we should have to regard the perihæmal system as a portion of the cœlom, which in the Pelmatozoa has reached only an incipient degree of specialisation, being in the region of the disc completely merged in the general body-cavity.

The account of the Holothurians has been written by Mr. E. S. Goodrich, who gives a useful summary of our present knowledge of the group. The remaining Eleutherozoa—Stelleroidea and Echinoidea—have been undertaken by Prof. J. W. Gregory, whose researches on these groups are well known to zoologists, and who gives us a most valuable and complete account of them. It is necessary, however, to point out a few errors or oversights which have crept in, some of which are important, though they do not detract from the value of the work as a whole. On p. 261 it is pointed out that we are indebted to Sladen for a memoir on the aberrant form *Astrophiura*, and the work is quoted in due course amongst the literature of Stelleroidea, but nowhere else is any reference made to *Astrophiura* and its peculiarities; it is omitted from the classification, does not appear in the index, and is, in fact, ignored altogether. The genus *Ophioteresis* is used as an argument for uniting the Asteroids and Ophiuroids on the ground that "the radial ambulacral vessels and nerve trunks lie in shallow grooves on the ventral surface of the anus" (p. 262; also pp. 270 and 274). The author gives no definite authority for this statement, but leaves us to infer that he obtains the fact from Bell's description of the genus. Bell, however, did not describe any such condition as that which Gregory dwells upon so often and makes the basis for such important deductions, and it is highly improbable that it occurs at all. It is much more probable the ambulacral vessels and nerve trunks pass in *Ophioteresis* through the aperture in the centre of the vertebral ossicle which Gregory figures plainly enough (Fig. xiv.), while maintaining a discreet silence about it. Finally, it must be mentioned that the peristomial plates in the Ophiuroid mouth skeleton are *not* "between the mouth frames and the buccal shields" (p. 264), but are above, *i.e.* to the aboral side of, the former, according, at least, to the careful descriptions and figures of Ludwig; the "mouth frames" are between the buccal shields and the peristomial plates.

A conscientious reviewer does his best to find mistakes in the works submitted to his scrutiny and judgment. In the present instance it cannot be said that we have been very successful in our search, having regard to the size and scope of the work. In conclusion, we can but congratulate heartily the editor, authors and publishers on the very valuable treatise they have produced, a work which reflects credit on all concerned, and is a triumph for English zoology.

E. A. M.

## THE BOTANY OF CAPTAIN COOK'S FIRST VOYAGE.

*Illustrations of the Botany of Captain Cook's Voyage Round the World in H.M.S. "Endeavour" in* 1768–71. By the Right Hon. Sir Joseph Banks and Dr. Daniel Solander, with Determinations by James Britten. Part I.: Australian Plants. 101 Plates, with descriptive letterpress. (London: Printed by order of the Trustees of the British Museum. All Booksellers. 1900.)

"BETTER late than never" may be said of the book the title of which is given above. It is a curious fact that the scientific results of several of the most important and most costly voyages of discovery, both English and foreign, have either not been published at all, or only in part, and in a fragmentary manner. Cook's first voyage is, perhaps, the most notable example of unfinished works of this kind in the history of British exploration. This is the more to be deplored, because collecting and methodical investigation were carried out on a scale previously unknown, and an immense sum was subsequently expended by Sir Joseph Banks in preparing the botanical results for publication. This is not the place to enter into the causes of the cessation of this part of the work: but it was not the only part that was long belated. It was not till 1893 that Captain Cook's own "Journal" was published, edited by Sir William Wharton; and three years later appeared Banks's "Journal" of that memorable voyage, edited by Sir Joseph Hooker. Although I have said "better late than never," it is obvious that the illustrations now in course of being issued have been, to some extent, forestalled, and the letterpress is historically interesting, rather than a contribution to science. According to the prospectus the complete work will comprise 800 plates; these will include a series illustrating the botanical collections of Cook's second voyage, when the Forsters, father and son, were the naturalists. Sydney Parkinson was the botanical artist on the first voyage, but he and the two other artists all died on the voyage, and their work was left in an unfinished condition. So much has been written about the plates now being issued and the desirability of their publication, that something superior to what they really are was probably expected by most people. Indeed it is difficult to suppress a feeling of disappointment. Compared with the botanical illustrations of other expeditions of discovery of a little later date, they are hard and unattractive, and floral dissections are almost entirely wanting. They lose, too, in effect, as they are transfers and not direct impressions of the original engravings on copper. The majority of the plates were engraved from drawings by F. P. Nodder, prepared from Parkinson's sketches and the dried specimens, and only the former name appears on the plates. Our remarks on this point, however, should be regarded in the light of explanation rather than criticism, because after all we must not forget that their publication has been delayed more than a century. Of course, it is highly regrettable that they were not published at the time, so that they might have been more fully utilised in the many publications that have appeared during the last century and a quarter on Australasian and Pacific Islands botany. A fact of great importance is that a comparatively small number of the plants here depicted had previously been figured. Mr. Britten has most conscientiously reproduced Solander's descriptions and remarks, even to the extent of palpable errors. Thus the locality Endeavour River is given throughout as Endeavour's River, and "petioli ½-uncialia," instead of unciales. But perhaps this course is more satisfactory than any attempt at improving the original; and errors of the latter kind may be due to slips of the transcriber. The keenest reader may overlook false terminations in Latin descriptions, and the most ready writer is apt to make them.

On the other hand, our thanks are due to Mr. Britten for much valuable information, and the correction of many current errors. Doubtless when the time comes for the "Introduction," some account will be given of the countries or districts explored, and the botanical results summarised.

With regard to nomenclature, it is fortunate that, although the rule of priority has been strictly followed, there are few suppressions of familiar names; but that is because there were few opportunities. Of course, the familiar names appear, but only as synonyms. Mr. Britten is an uncompromising disciple of the school of reformers, and he has been permitted to exercise his will in this national publication. Thus *Ionidium* becomes *Calceolaria;* and the calceolarias that everybody is familiar with have *Fagelia* for their generic name. *Cosmia* takes the place of *Calandrinia; Damapana* that of *Smithia;* and *Caulinia* that of *Kennedya.* The complications that such changes cause are almost interminable, as the revival of one name may affect half-a-dozen other well-established generic appellations. But this is not the place to discuss the question. Botanists will be thankful to the Trustees of the British Museum for this valuable addition to their pictorial books, which is at the same time a monument to some of the scientific pioneers in British exploration.

W. BOTTING HEMSLEY.

## OUR BOOK SHELF.

*Fancy Water-Fowl.* By F. Finn. Pp. 45. Illustrated. (London: *Feathered World* Office, 1900.)

MR. FINN, especially to Indian readers, is such a well-known writer on popular ornithology in more than one journal that the reproduction of a series of his articles in book-form can scarcely fail to be welcomed by a wide circle. And in selecting ornamental, or "fancy," water-fowl as a subject, he has hit upon one which appeals to a large number of bird lovers, if for no other reason than the facility with which these handsome birds can be reared and kept in confinement, even when the available space is limited.

The author has confined himself, on the advice of a lady friend, to well-known species, and in the selection he has made he is, on the whole, to be congratulated. We should, however, have liked to see mention made of the so-called Coscoroba Swan of South America, on account of its very peculiar organisation, although we are well aware that, chiefly owing to its delicate constitution, it is seldom seen in European collections.

Both the illustrations and the text have been reproduced in their original guise from the *Feathered World.* With regard to the page plates there is considerable individual variation in their degrees of excellence, the figure of the Spotted-bill Duck, forming the frontispiece, being decidedly superior to that of Rosy-billed Pochards which comes later, the last-mentioned being somewhat coarse and blurred in outline. Indeed, we venture to think that if a second edition be called for it would be a decided improvement if the plates were photographed down to octavo size, while at the same time the text might be printed in larger type.

As it is, however, the book is decidedly attractive, and ought to prove indispensable to all breeders of ornamental water-fowl. R. L.

*Catalogue of Eastern and Australian Lepidoptera Heterocera in the Collection of the Oxford University Museum.* Part ii. Noctuina, Geometrina and Pyralidina. By Col. C. Swinhoe. Pterophoridæ and Tineina. By the Right Hon. Lord Walsingham and John Hartley Durrant. Pp. vi + 630; with 8 plates. (Oxford: Clarendon Press, 1900.)

THE first volume of this important work was published as long ago as 1892; it included the Sphinges and Bombyces; and the second and concluding volume, which is nearly twice as thick as the first, has at length been issued.

A great number of *Lepidoptera Heterocera* (moths) were described by the late Francis Walker, not only from the British Museum, but from various private collections, chiefly from that of W. Wilson Saunders. After the death of the latter, large portions of his collection found their way into the Oxford Museum, and the types have now been carefully identified, and a considerable number figured. This is extremely important, as it will enable lepidopterists at a distance to identify species with more certainty than by descriptions alone; and a figure also helps to fix the identity of a species in case the type should be lost or destroyed.

About 2340 species of moths are enumerated in the present volume, and we note that in addition to Walker's types many described by Mr. F. Moore and other entomologists are likewise contained in the Oxford Museum; nor must we omit to mention that several new genera and species are described and figured by the authors of the Catalogue for the first time. However, the work is one which, notwithstanding its importance, appeals so exclusively to specialists that a more lengthy notice is hardly required in the columns of NATURE.

W. F. K.

*Sir Stamford Raffles: England in the Far East.* By H. E. Egerton, M.A. Pp. xx + 290. (London: Unwin, 1900.)

THIS volume, which is one of a series, entitled "Builders of Greater Britain," and edited by Mr. H. F. Wilson, does not call for much comment in a journal devoted to science. The author of the biography naturally deals mainly with Sir Stamford Raffles as an administrator in the Straits Settlements and the Malay Archipelago, and only incidentally, and that very briefly, refers to him as a zoologist. Raffles was, as everybody knows, one of the founders, and the first president, of the Zoological Society of London; and his bust adorns the lion house of that society. Mr. Egerton, in narrating this fact, is chiefly impressed by "how much innocent pleasure this distinguished child-lover has given to countless thousands of children" by his successful efforts in this direction. He mentions, however, the collections which he took care to make, and which were largely reported upon by Dr. Horsfield. In those days much that was brought back from the East in the way of zoological specimens was quite new to science, and the animals had to have names given to them; it is not such a great compliment as Mr. Egerton seems to think to name a species *Gymnura rafflesii*, after Sir Stamford. This compliment is usually paid to the capturer of a new form, and it is ridiculous to say that "Raffles' reputation in the scientific world is attested by the fact that the great French naturalist, M. Geoffroy St. Hilaire, described a new variety of animal under the specific name 'Rafflesii.'"

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### The Teaching of Mathematics.

PROF. JOHN PERRY has asked me to write something in criticism of the views he has lately expressed about the teaching of mathematics. I am inclined to ask, What is the use? He knows my views pretty well, and others too; and those who don't can learn them if they want to by buying my books. That is the best way, as it brings in one-and-threepences, and so does some good. I think there is a great deal to be said on both sides, and that if you are a born logic-chopper you will think differently from Faraday. The subject is too large, and I will only offer a few remarks about the teaching of geometry, based upon my own experience and observations. Euclid is the worst. It is shocking that young people should be addling their brains over mere logical subtleties, trying to understand the proof of one obvious fact in terms of something equally, or, it may be, not quite so obvious, and conceiving a profound dislike for mathematics, when they might be learning geometry, a most important fundamental subject, which can be made very interesting and instructive. I hold the view that it is essentially an experimental science, like any other, and should be taught observationally, descriptively and experimentally in the first place. The teaching should be a natural continuation of that education in geometry which every child undergoes by contact with his surroundings, only, of course, made definite and purposeful. It should be a teaching of the broad facts of geometry as they really exist, so as to impart an all-round knowledge of the subject. It should be Solid as well as Plane; the sphere and cube, &c., as well as the usual circle and square; models, sections, diagrams, compasses, rulers, &c., every aid that is useful and practical should be given. And it should be quantitative as well. The value of $\pi$ should be *measured*; it may be done to a high degree of accuracy. So with the area of the circle, ellipse and all sorts of other things. The famous 47th. The boy who really measures and finds it true will have grasped the fact far better than by a logical demonstration without adequate experimental knowledge; for it happens that boys, who are generally very stupid in abstract ideas, learn a demonstration without knowing what it is all about in an intelligent manner. It may be said by logicians that you do not *prove* anything in this way. I differ. It might equally well be said that you prove nothing by *any* physical measurements. You have really proved the most important part. What a so-called rigorous proof amounts to is only this, that by limitation and substitution, arguing about abstract perfect circles, &c., replacing the practical ones, you can be as precise as you please. Now when a boy has learnt geometry, and has become competent to reason about its connections, he may pass on to the theory of the subject. Even then it should not be in Euclidean style; let the invaluable assistance of arithmetic and algebra be invoked, and the most useful idea of the vector be made prominent. I feel quite certain that I am right in this question of the teaching of geometry, having gone through it at school, where I made the closest observations on the effect of Euclid upon the rest of them. It was a sad farce, though conducted by a conscientious, hard-working teacher. Two or three followed, and were made temporarily into conceited logic-choppers, contradicting their parents; the effect upon most of the rest was disheartening and demoralising. I also feel quite certain about the experiential and experimental basis of space geometry, though that opinion has been of slow growth. If I understand them rightly, it is generally believed by mathematicians that geometry is pre-existent in the human mind, and that all we do is to look at nature and observe an approximate resemblance to the properties of the ideal space. You might assert the same pre-existence of dynamics or chemistry. I think it is a complete reversal of the natural order of ideas. It seems to me that geometry is only pre-existent in this limited sense; that since we are the children of many fathers and mothers, all of whom grew up and developed their minds (so far as they went) in contact with nature, of which they were a part, so our brains have grown to suit. So the child takes in the facts of space geometry naturally and easily. The experience of past generations makes the acquisition of present experience easier, and so it comes about that we cannot help seeing it. But it is all experience, after all; although learned philosophers, by long, long thinking over the theory of groups and other abstruse high developments, may perhaps come to what I think is a sort of self-deception, and think that their geometry is pre-existent in themselves, whilst nature's is only a bad copy. Like the old Indian pundit, whose name was something like Bhatravistra, who, after fifty years inward contemplation, discovered God;—where—it would not be polite to mention. OLIVER HEAVISIDE.

September 22.

### The New Senate of the University of London.

IN your paragraph (NATURE, September 27, p. 543) on the new Senate about to be elected in the University of London, you have put the issue as it has occurred to me. I have not been able to give my support to either of the two bodies which have set their electoral machinery in motion, for the simple reason that neither of them has produced a list of names of candidates in which higher educational work is adequately represented. I thoroughly endorse your remark that "It would be nothing less than a calamity were Convocation to elect sixteen irreconcilables with no idea outside that of introducing the peculiar needs of the external student into all deliberations of the Senate."

The University may boast of the value of the degree; but this is only to say that as an organism its *cell*-life is strong. As an organism, however, its *somatic* life is weak; and the *summation and co-ordination of function* is the main idea for the new Senate of the University to keep before it, if the University is to be a factor of real power in our national and imperial life in the centuries to come. An experience as a teacher of over a quarter of a century (Wellington College and Nottingham) entitles me, I think, to speak on this matter.

Bishop's Stortford, September 28. A. IRVING.

### The Peopling of Australia.

IN the issue of NATURE dated December 28, 1899, there appeared a notice of my book, "Eaglehawk and Crow," from the pen of Prof. A. C. Haddon. A copy did not reach me till the end of February, and for that and other reasons which need not be mentioned I delayed replying to the criticisms passed. With your kind permission I shall now endeavour to meet the principal objections raised to my work, with a desire of advancing, if even in a very small measure, our knowledge of Australian ethnology. All ethnologists are agreed upon the difficulty of the Australian problem, and no one who attempts to solve it will be surprised at their agreement.

I regret that, owing to my omitting to define my use of the term Melanesian, Prof. Haddon misapprehended one of my fundamental positions. In a note on page 5 I say, "Papuan is applied, not in its narrowest application (dark New Guinean), but as the equivalent of Melanesian, and is meant to include the Tasmanian aborigines, &c." From this Prof. Haddon inferred that I excluded the Papuans proper from my Papuan race. Nothing was further from my intention. I included them as a sub-race under the wider term Melanesian, as many writers have done, as even the latest writer on the subject, Deniker, has done in his "Races of Man," page 285, and elsewhere. The basis of my ethnological position may be thus represented:—

- Papuan or Melanesian Race.
  - Papuan Proper.
  - Malanesian Proper.
  - Tasmanian Papuan.
    - Primitive Australian.
    - Tasmanian.

This classification underlies my whole book. I confess that I would now prefer to restrict the name Melanesian to the Melanesians proper as less liable to ambiguity, but in making Melanesian the general name I followed the lead of others much more competent than I am. That I recognised the narrower application of Papuan is evident from the above quotation from page 5, and such a passage as the following shows that I recognise Melanesians proper. "There are indications of groups of Melanesians having reached Australia on the eastern Queensland coast," page 73. Further, I invariably refer to the Tasmanians as Papuans, with occasionally some such qualifying word as *primitive*.

My solution of the Australian racial problem having received the approval of Prof. Keane ("Ethnology," pp. 291–2), I may state it briefly here. The now extinct Tasmanians represent the primeval Australian aborigines. They were probably not a pure race, but embraced Negrito and Papuan elements. At the time of their arrival in Australia they probably occupied the islands to the north, and their congeners were the first to occupy Melanesia. Upon the primitive Papuans there was a strong graft of what, for want of a better name, and following the example of others, I have called "Dravidians," using this as a term of convenience to indicate likeness to the people of southern and central India. Then followed a further migration, in a desultory manner, of people of Malay stock; the precise locality whence these came is indeterminable, but I give evidence of distinctly Sumatran influence in the north-west. Concurrently, or subsequently, companies of Melanesians proper and Papuans proper have mingled with the Australians on the north and east of Queensland.

The two earliest immigrations entered Australia from New Guinea or neighbourhood. The population became distributed by streams diverging from the base of Cape York Peninsula.

When allowance has been made for Prof. Haddon's misconception of my use of the term Papuan, there is little more in his notice that needs to be referred to, as he concedes my main positions.

Mr. S. H. Ray, having been invited by Prof. Haddon to offer observations upon the linguistic part of the work, criticised it in a manner which seems to be unnecessarily caustic, fastening attention upon petty points which he objected to, and ignoring the main issues. He begins by asserting that I belong to a school of Australian pseudo-philologists who believe that a likeness of words in sound and meaning is a proof of common origin, and this in spite of my explicit disavowal of such a position, and my exposure of the unsoundness of it on page 44, where I show that on such a principle the Australian languages might be derived from the English. Having made so fair a start with a *petitio principii*, by gross misrepresentation of my statements, he proceeds to buttress his assertion. "We are asked to believe," he continues, "that Malay immigrants, presumably from various parts of the Archipelago, entered Australia from the north, and wandering about the interior, scattered 'astonishing relics' of the speech of one of their sections all over the island continent." He is not asked to believe any such ridiculous nonsense, and it is singularly disingenuous to say so in the face of my sober statements on page 57, "Either the Malay inroad, if made at the north, took place in long past ages, or now and again parties of Malays, either from choice or necessity, landed and became naturalised at various spots on the east, north and west, and modified the speech of the people, first immediately round them, and then landwards": and on page 61, "This last influx (the Malay) may have come by several little rills, entering at places widely apart and gradually losing themselves in the life-lake." The "wandering about the interior" is a pure invention of Mr. Ray's. When the universal practice of exogamy is taken into account, along with the general pressure and movement of people, language, customs, &c., from north to south, my theory of Malay influence on the Australian people and language will be accepted as reasonable by unprejudiced minds. In the *Journal* of the Anthropological Institute for 1894–5, in a paper on "The Languages of British New Guinea," this very Mr. Ray uses language, and language alone, as a basis of classification for proving racial distinctions and affinities and movements. I do not say that this was an improper use of the linguistic argument, but it differs from mine in this, that I rarely rely upon language alone. I back up the linguistic evidence by that of other ethnological characters.

To come to particulars: my identifying a certain type of Australian words for "Head" with the Malay "Kapala" is objected to because "Kapala" is a word of Indian origin. But the word has been current in Malay for five or six centuries, and is in use in that very part of Sumatra from which, according to my hypothesis, came the authors of the best Australian rock-paintings. It is quite possible that I may be mistaken in relating certain Australian words to "Kapala," but Mr. Ray's ground of objection has little or no cogency.

"Mama" and "bapa" are terms for mother and father of wide currency in Australia. The former I connect with early Papuan influence, the latter more especially with Malay. He objects on the ground that connectives of "mama" are more common in the Malay districts of the Eastern Archipelago than "bapa." But in Australia the word "mama" occurs only in the extreme S.W. and S.E., among the purest modern representatives of the earliest occupants of Australia, thus affording ground for the conclusion that the term "mama" preceded the term "bapa." The wide prevalence of "bapa" forms in other countries I myself refer to on page 44; but the question is, What race was specially influential in giving such forms currency in Australia? As against my position it is not sufficient for Mr. Ray to say that "mama" variants are of more frequent occurrence in Malay centres than "bapa" variants, he will have to prove that the words of "mama" type are not adopted words in Malay, were not earlier in use in the East Indian Archipelago than the other type of words, and are not more markedly Papuan than these.

Mr. Ray complains that individual words in the languages quoted "are not always accurately given or properly understood." This may be; but like himself I am dependent upon my authorities. When further on he suggests that I might have attempted uniformity of spelling in the foreign words, he is like the "children sitting in the market-place." A desire to be free from suspicion of tampering with my borrowed materials kept me from applying to them a uniform system of spelling, and evidently my caution was not unnecessary.

Mr. Ray's harshness is all the more indefensible since he himself falls demonstrably into error on the very point upon which he proposes to correct me. As proof of my mistaking the form and meaning of words, he cites the New Guinea numerals (pp. 165, 169). He says they are explainable compounds. He does not, however, attempt to explain them. But even if they are, this fact alone does not prove that they could not be transmitted to Australia. One feature about Australian numerals is clearly shown in my tables, viz. that they occur geographically in lines that converge on Cape York Peninsula. Some of them are most certainly identical with forms in use on Saibai Island on the New Guinea coast, *e.g.* "woorba," with variants traceable along the Queensland coast from a point about 1000 miles S.E. of Cape York, and represented in the form "warapune" Prince of Wales Island, "woorapoo" at Warrior Island, and in "urapon" at Saibai. One numeral, "luadi" (two), used by the Kalkadoon tribe, whose territory is about 150 miles south of the Gulf of Carpentaria and some 600 miles S.W. of Cape York, is a Melanesian numeral. It did not fly that distance through the air. And there is just as little doubt about the identity of at least several of the other Australian numerals with the New Guinea forms to which I have related them. My table of numerals was not formed rashly. It will be worth Mr. Ray's while to examine and test it carefully. The convergence of numerals upon Cape York Peninsula is only one striking illustration of what occurs in the case of other words, and words thus traced to the very coast must have come from New Guinea and adjacent islands.

As another example of my misunderstanding words, Mr. Ray refers to my "ori kaiza," pp. 66–7. He says: "Ori kaiza" is mongrel, "ori" (bird) is Toaripi, Papuan Gulf, and "kaiza" (big thing) is Saibai, West Torres Straits. This is, for himself, a most unfortunate example. Although he speaks so authoritatively, he is utterly at fault. Sir W. MacGregor's reports give "uroi" (bird) as a Saibai word; and even Mr. Ray himself, in his paper already quoted from, gives "urui" as Saibai for 'bird,' a fact he appears to have forgotten. Besides, in the "Voyage of the *Rattlesnake*," containing vocabularies obtained in 1849 from a white woman who had been among the natives for four and a half years, McGillivray gives "wuroi" as a Cape York word, and "ure" as a Kowrarega word, both meaning bird. Mr. Ray's assertion, therefore, that "ori kaiza" is mongrel, is contrary to fact, and my tracing of this compound word across Australia from S.W. to N.E., and to the New Guinea coast, is not in the least invalidated by Mr. Ray's groundless and inconsistent statement that the word is mongrel.

Mr. Ray characterises my comparison of Australian words with Malay and New Hebridean as "absurd and misleading." This may be so to one with his pre-conceptions, but certainly not from the point of view which I have taken of the relation subsisting between the races whose words are compared. If the Tasmanians were the original occupants, both of Australia and the greater part of Melanesia, which is my hypothesis, it is not unreasonable to suppose that certain radicals would be common to Tasmanians, Australians and Melanesians proper. And further, one of the most competent authorities on the Oceanic languages, the Rev. Dr. MacDonald, of Efate, is of opinion that Malay, Melanesian and Polynesian are sister languages derived originally from one mother tongue. If he be right, there would be no absurdity in affirming analogies between Malay and New Hebridean words. But I have included the Malay with a note almost like an apology. I only cite eight Malay words, and the only conclusions I draw concerning the Malay in this connection is "The terms for father, skin, are the same in Malay, Australian and New Hebridean" (page 156).

I would have liked to have shown that the Melanesians proper have had much more influence upon the Australians than Mr. Ray seems to have any conception of, but I have already taken up so much space that I must content myself with saying that this proposition can be successfully maintained, and with your indulgence I hope in a future letter to make good my words. In conclusion, I would just say that I welcome fair and sound criticism based on accurate knowledge for its influence in promoting truth, but mere fault-finding and ridicule can benefit neither authors nor readers. One sentence from my reviewer in the *Saturday Review* may not be out of place here:—"If Mr. Mathew has not proved his theories to the satisfaction of all his readers, it is not from lack of knowledge or scientific methods, but from the imperfection of his materials."

Coburg, Victoria, August 16. JOHN MATHEW.

---

## *THE PRESERVATION OF BIG GAME IN AFRICA.*

PAST experience in America and South Africa shows how rapidly the teeming millions born of the soil may be shot out. Writers of half a century ago describe on the veldt in South Africa a paradise of varied life, which is now irretrievably lost, through the carelessness and wastefulness of white men. Some species have absolutely disappeared, never to be seen again on the face of the earth. Others are so scarce that it is doubtful whether their power of reproduction can save the race. The fact that an International Conference, attended by delegates from Germany, France, Italy, Portugal and the Congo Free State, on the subject of the preservation of the game from destruction in Africa, met recently in London, under the auspices of our Foreign Office, shows that a widespread interest is now taken in this subject. Let us see how the matter stood previous to the meeting of the Conference—at least as regards British territory.

Excluding the settled parts of South Africa which were outside the purview of the Conference, we may observe, in the first place, that our Foreign Office appears to be thoroughly alive to the urgency of the question in those territories under their jurisdiction. They had enacted game regulations which ought to have been effective for their purpose. A 25*l.* license was imposed upon strangers, and one of 3*l.* upon residents and officials, as a necessary condition of shooting, while the licensees were limited to two specimens in the case of elephants, rhinoceros, hippopotamus, buffalo and giraffe. Fines up to 500 rupees, and imprisonment for two months, were the maximum penalties. Above all, Reserves for the game were defined. Similar regulations to the above were in force in German territory; but let us confine our attention to British East Africa as an example with which I am familiar. Here, on the best feeding grounds, there are vast herds of wildebeest, hartebeest, impala, zebras, gazelles of several species, and in lesser numbers water-buck, giraffes and rhinoceros. All these, and others, may be seen from the windows of the train as it traverses the new Uganda railway, which has now been constructed to a point about two-thirds of the way to Lake Victoria. The Kenia province, which is about 100 miles by 40, has been constituted a game Reserve. Other Reserves have been established in Uganda and British Central Africa. Each of the Foreign Powers engaged in the Conference have bound themselves to provide similar Reserves where they have not already done so, and to maintain them as such with strictness, and much depends upon the interpretation of that word. Now this is just what we had not until recently done in the case of the Kenia Reserve.

One of the regulations provides "That public officers may be specially authorised to kill, &c." in that Reserve. Unfortunately the words "may be authorised" in this regulation were interpreted by many of the Protectorate and railway officers stationed at Nyrobe, Kikuyu and elsewhere as "are authorised," and thus as making them free of the Reserve. This laxity of interpretation had a tendency to spread, and large quantities of game were at first killed there after the arrival of the railway. A Reserve is no true Reserve which is subject to personal exceptions, and in the circumstances which I have detailed was a delusion and of little value. We may rest assured that, now that this defect has been pointed out, the Foreign Office will not be backward to remedy it; and even if it were not so, they are under an international obligation to make the Reserve a reality. We may, therefore, confidently expect that the words I have quoted, which admit of a serious leakage, will disappear. It must not be thought that the officers to whom I have referred are indifferent to the preservation of game. It is in their interest, above all others, that these regulations should be maintained, and I am confident that the good sportsmen, of whom there are many among them, are anxious to be protected against those who cannot be so described. Nothing can be stronger than their reprobation of the worst transgressors, as, for instance, of a gentleman wearing her Majesty's uniform, who, I was told, killed approximately a score of wildebeest in a day, and left them rotting on the ground. The author of this disgusting butchery was brought to book, but he passed into Uganda, and thus, sheltered by a technicality, escaped the payment of the fine. It is to be hoped that the long arm of the autocratic committee which governs both territories will ultimately reach this glaring offender.

It remains to be considered in what respects the recommendations of the Convention will strengthen the game laws in their present form. The principal recommendations of the Conference may be summarised as follows. A special and select list of animals are to be absolutely protected at all times. Another schedule comprises the species which are to receive protection for immature animals and breeding females. The sale of tusks of elephants weighing less than eleven pounds is forbidden, and finally each Power undertakes to establish adequate Reserves and to protect them from encroachment. It will be seen that these recommendations impose upon them certain obligations, and we may thus expect that the new regulations for the British territories will include a schedule of animals as sacred from molestation as the bulls of Apis. The giraffe, eland and buffalo are, at any rate, among those which are sure to enjoy this royal distinction. It is a little difficult to see why vultures, owls and rhinoceros birds, which are exceedingly useful, but are not sought for food, should have been added by the Conference to such a distinguished list. The second list, of which the breeders and young are to be protected, will doubtless include such animals as rhinoceros, hippopotamus, waterbuck, sable, greater and lesser koodoo. The importance of this will be seen when it is remembered how slowly these larger animals breed. Apart from these restrictions a limit will doubtless be placed on the numbers of all the game animals allowed to be killed under each license, a high limit being given for the common species, and a much lower one, probably not exceeding two specimens, for those in most danger of disappearance.

Infractions of this rule may be somewhat difficult to detect, but every licensee, at the expiry of his license, should be required to furnish a return of what he has killed. This would impose a certain restraint on thoughtless sportsmen, and when the returns are collated would form a basis for a valuable tabulation of the numbers of each species killed from year to year, and serve as an indication of the increase or diminution of any species in a given area. A small export duty on skins and horns would be a useful assistance to such a return.

The maintenance of Reserves is of the highest importance for the preservation of the various species. In my opinion, the position and boundaries of the Kenia Reserve, which is perhaps the most important of all, should be reconsidered. These boundaries were selected because they happened to be the defined limits of a Province, and not because they represented the real needs of the game. A large portion of the area is densely populated and cultivated. Another considerable area is at a high elevation and covered with forest which harbours some elephants; but is of no use to the great families of grass feeders, such as the zebras, the numerous kinds of antelope and gazelle, the rhinoceros and ostrich. The great bulk of these are confined to the grass plains along the Athi River, and unfortunately its left bank only is within the Reserve. This feeding area is thus but a small fraction of the whole Reserve, and is quite inadequate to feed the vast herds; nor does it, as a matter of fact, cover their frequent migrations in search of fresh grazing, which extends to both sides of the Athi, and southwards to the plains of Kilimanjaro. The limited belt of grazing ground within the Reserve has been still further curtailed by the location of the important railway centre of Nyrobe in the midst of it, since the Reserve was constituted. This will necessarily drive the game from that part of the protected plains. It is therefore desirable that the boundaries of the Reserve should be reconsidered by competent officers on the spot, not forgetting the important assistance which would be rendered by the railway in safeguarding and watching it, provided it traverses it or skirts its boundary on one side.

Then as to the difficult question of elephants, difficult because of the high money value of their tusks. I am personally opposed to the destruction of elephants at all, on the ground that, valuable as they are for their ivory, that will soon come to an end at the present rate of destruction, and that they might be still more valuable as weight-carriers. That is, perhaps, a counsel of perfection, but that they require some far more effective protection is obvious to every one who has studied the subject. Recently an Englishman sold in Mombasa the produce of his trip in ivory for 8000*l*. The hundreds of elephants necessary to produce this amount were, of course, not in the main killed by his own rifle. Some of the ivory may have been bought, but numbers of native hunters were said to have been hired for this purpose and attached to his staff, and were sent far and wide over the country. Thus this caravan must have left a broad trail of destruction for hundreds of miles. When the wealthy and powerful set such an example, how can the law be enforced against those who have the excuse of poverty. It is to be hoped that the Foreign Office will be able to devise means for the arrest of wholesale destruction like this. Although the Convention has not recommended it, is it too much to hope for the imposition of an adequate export duty, uniform at all the ports of exit, to whatever Power they may belong, and the total prohibition of the export of cow ivory?

The question of bringing resident natives under the prohibition which extend to Europeans requires to be carefully weighed. In my opinion, it is neither possible or just to stop their hunting so long as they are confined to their primitive weapon, the poisoned arrow. From time immemorial the destruction caused by the indigenous inhabitants has not appreciably diminished the stock. The land and the animals upon it are their birthright, and to interfere with it would surely cause trouble. We are not bound, however, to furnish them with civilised weapons, and every precaution should be taken to prevent their obtaining them.

Finally, the best of rules are useless without two things —a sound public opinion among the resident whites whom they chiefly affect, and a firm and knowledgable man to carry them out. The first exists, and I am convinced is on the increase. How should it be otherwise, unless one presupposes the most shortsighted selfishness? As to enforcing the rules, that which is the business of several officials, all of whom are engaged in office work, is practically no one's business. Let there be one man on the spot—that is to say one in each great game district, and especially in each Reserve—whose duty it is to know and to act. E. N. BUXTON.

## *NOTES.*

As was announced in our last issue, many of the medical schools in London and elsewhere were re-opened this week, and addresses were delivered by well-known medical men and men of science. At the Charing Cross Hospital Medical School the third Huxley Lecture was delivered by Lord Lister on Tuesday.

A COURSE of twelve "Swiney" lectures on "Extinct and Persistent Types" will be delivered in the lecture theatre of the Victoria and Albert Museum, South Kensington, by Dr. R. H. Traquair, F.R.S., on Tuesdays, Wednesdays, and Fridays from October 9 to November 2. No charge is made for admission to the lectures.

AT the meeting of the Royal Photographic Society to be held on Tuesday next, October 9, the President will deliver his annual address, and present the medals awarded at the Society's Exhibition.

THE Lettsomian lectures will be delivered before the Medical Society of London in March and April next, and the oration will be given in May by Mr. F. Richardson Cross.

THE seventeenth annual meeting of the Association of Official Agricultural Chemists is to be held at the Columbian University of Washington, commencing on Friday, November 16 next.

THE fourteenth International Medical Congress will be held at Madrid early in 1903, under the presidency of Prof. Julien Calleja.

THE annual "Fungus Foray" of the Essex Field Club will take place on Saturday next from High Beach, Epping Forest. The prospective arrangements of the club include the opening of the Essex Museum of Natural History by the Countess of Warwick, on the 18th inst. The scientific winter evening meetings will be resumed in the Physical Lecture Theatre of the West Ham Technical Institute on October 27.

*Science* announces that Prof. H. T. Todd, having reached the age limit, has retired from the Directorship of the U.S. Nautical Almanac. Prof. S. J. Brown, astronomical director of the U S. Naval Observatory, has undertaken the duties of the office.

ACCORDING to the *Lancet*, a scheme has been sanctioned by the Charity Commissioners by which 644*l*. left to the Royal College of Surgeons of England in 1884 will be devoted to providing every four years a "Cartwright Medal" for an essay on dental surgery. The medal will be accompanied by an honorarium.

THE gold medal of the American Philosophical Society, known as the Magellanic, will be awarded in December next for the best discovery or most useful invention in the physical sciences brought before the Society before November 1.

PROF. F. KLEIN has been awarded 800 marks by the Göttingen Society of Sciences for his Mathematical Encyclopædia, and the same society has awarded 500 marks to Prof. Wiecherts for that worker's seismological recording instruments.

IN addition to the medals and prizes given for communications discussed at the meetings of the Institution of Civil Engineers in the past session, the Institution has made a number of other awards in respect of other papers dealt with during the same period, *e.g.* a George Stephenson medal and a Telford premium to Mr. L. F. Vernon Harcourt, and Telford premiums to seven other gentlemen. For students' papers, the James Forrest medal and a Miller prize have been awarded to Mr. C. B. Fox, the James Prescott Joule medal and a Miller prize to Mr. J. W. Smith, and Miller prizes to four other students. The council have nominated Mr. R. F. Whitehead to the Palmer scholarship at the University of Cambridge in succession to Mr. A. H. Kirby.

A NEW technical school is to be erected in Belfast on a portion of the grounds purchased from the Royal Academical Institution, and a principal is to be appointed shortly at a salary of 600*l*. per annum, whose experienced practical advice will, it is hoped, be of much value in making the interior arrangements of the building, and in organising the work of the institution while the building operations are in progress.

PROPERTY valued at upwards of 200,000 dollars has been left by Mr. Charles H. Smith for the maintenance of the botanical specimens in the city park of Providence, Rhode Island.

WE have had pleasure on more than one occasion to refer to the good work that is being done to the cause of scientific education by the Essex Technical Instruction Committee, and are glad now to call attention to two new courses of lectures that are about to be inaugurated by the committee. A first-year's course of instruction in botany for teachers will commence at Chelmsford on Saturday, October 6, and will be continued on successive Saturdays until about the middle of May, 1901, and an elementary course of practical instruction in dairy bacteriology will commence on Thursday, October 11, and will be continued on ten consecutive Thursdays.

THE *Windward*, according to *Science*, was expected to reach St. John's by about the middle of September, but a short delay would not be surprising as the vessel started late, owing to some difficulty with the machinery, and was subsequently delayed by ice along the coast of Labrador. The arrival of the steamship is awaited with interest and some anxiety, as news will be brought, not only of the return of Peary, but also of Captain Sverdrup and Dr. Stein. The former has the *Fram* provisioned for five years, with a crew of twelve men. He planned to round the northern boundary of Greenland and to make his way down its unknown east coast to Cape Bismarck. It is said that the expedition under Dr. Robert Stein of the U.S. Geological Survey, who is accompanied by Mr. Leopold Kann, of Cornell University and Mr. Samuel Warmbath of Harvard University, was poorly equipped and left in a dangerous position. Lieut. Peary himself expected to establish his last depôt at Cape Hecla, the most northerly point of Grinnell Land just beyond the 82nd parallel, whence he intended to advance with Eskimo and sleds as far north as possible.

AT a meeting held on June 12 last at the University o Melbourne, it was unanimously resolved to form a society to be called the Society of Chemical Industry of Victoria, the objects for the establishment of the society being: (*a*) to afford its members opportunities of meeting and discussing matters connected with applied and industrial chemistry; (*b*) generally to advance the cause of chemical industry in Victoria. It was further resolved that meetings shall be held at monthly intervals during the greater part of the year, at which papers on special branches of industrial chemistry are to be read and discussed. At a subsequent meeting, Prof. Orme Masson was elected president. The first paper to be read before the Society was one by Mr. D. Avery on September 4, on the cyanide process for gold extraction. The Society has made an encouraging start, as up to the end of August 118 members had been enrolled. We trust a lengthy and prosperous career lies before the new arrival.

THE sixteenth session of the Queensland branch of the Royal Geographical Society of Australasia was inaugurated at Brisbane on August 17, when a paper was read by the secretary—Mr. J. R. Thomson—on the geographical evolution of the Australian Continent. In connection with the society it has been decided to award a medal annually for the best and most scientific paper on some subject dealing with Queensland, and a fund for this purpose has been opened.

THE seventy-second annual meeting of the Association of German Naturalists and Physicians opened on September 17 at Aix-la-Chapelle with an attendance of about two thousand members. Of the thirty-eight sections, seventeen are devoted to such subjects as natural history, geology, geography, education, &c., the remaining twenty-one dealing with all the special subjects of medicine, including balneology, accidents, history of medicine and medical geography, and finally veterinary matters. A special correspondent of the *British Medical Journal* states that at the opening meeting the usual speeches of welcome were delivered by the Mayor and others, and the introductory addresses this year were by arrangement devoted, not only to giving a retrospect of the subject, but also to a sketch of its development during the nineteenth century. Dr. J. H. van 't Hoff spoke on the development of the exact natural sciences (natural history, chemistry and allied subjects). Dr. G. Hertwig delivered an address on the evolution of biology, in which, after relating anatomical discoveries, he came to the large question of the natural origin of the organic world. He considered that theories as to inheritance and natural selection still rested on the uncertain basis of hypothesis. He pointed out, however, that the difficulty arose from the absence of sufficient prehistoric records, and expressed his agreement with the opinion of Huxley that Darwin's teaching as to evolution will survive, apart from his principles of selection. Prof. Naunyn gave an address on the evolution of medicine, connecting the progress of the science with the names of Schwann, Pasteur, and Lister. The fourth and last address was given by Prof. Chiari, whose subject was the evolution of pathological anatomy.

THE British Mycological Society and the Cryptogamic Society of Scotland held a most successful meeting at the Boat of Garten from September 17 to 22. Various portions of the old forests of Rothiemurchus and Abernethy were worked from day to day, and a rich collection of scarce Hydnei and Cortinarii was secured. Prof. Marshall Ward (President of the British Society) gave an address, entitled "Nutrition of Fungi," and also contributed a paper on "Naematelia." Exeter was selected as the centre for next year's foray in the last week in September, and Prof. Marshall Ward was re-elected President.

AT the annual meeting of the Hull Scientific and Field Naturalists' Club, on September 26, an active and successful year of work was reported. A committee has been formed to work in connection with the National Trust for Places of Historic Interest or Natural Beauty; several important "finds" have been made during the weekly excursions; an exhibition of local natural history, geological and archæological specimens has been held in the Technical Schools; and the Club has become a Corresponding Society of the British Association.

EVERY one interested in astronomy will welcome the new publication *Astronomischer Jahresbericht*, the first volume of which, for the year 1899, has recently made its appearance. This important yearly volume is published by Herr Walter F. Wislicenus with the aid of the *Astronomischen Gesellschaft*, and printed in Berlin (Druck und Verlag von Georg Reimer, 1900, pp. 536). The object of this volume is to present to astronomical readers a brief summary of the contents of every publication, whether it be in book, article or pamphlet form, which treats of any matter connected with theoretical or practical astronomy, or with researches in astrophysics. The project is a great one, and with careful attention could be carried out successfully. This, the initial volume, reflects great credit on Herr Wislicenus, who, although associated with five other workers, seems to have laboured nobly and undertaken the greater part of the volume. The subject-matter is divided into four main sections, namely:—General and historical; astronomy, which includes spherical, orbit determinations, celestial mechanics, instruments and methods of observation, and, lastly, observations; astrophysics; and geodesy and nautical astronomy. The work is made complete by an excellent table of contents, and an index of names and the full titles of works referred to are given in each case. The author hopes that for future volumes he will have the help of all well-wishers of this work, and that such help will take the form of either references to published works or the works themselves, especially when they appear in transactions of societies which are published too late for insertion in the yearly volume, or other publications which are not specially devoted to astronomical matters. A glance at the present volume is sufficient to show the utility and value of this work, and it should be found in every astronomical observatory and laboratory.

QUOTING from the *Botanical Gazette*, *Science* says that the private herbarium of Mr. Harry N. Patterson, of Oquawka, Illinois, containing about 30,000 sheets, has been secured by the Field Columbian Museum, and will be installed as promptly as careful cataloguing will admit. The botanical department of the museum is, says our contemporary, to be congratulated upon this accession of one of the notable private herbaria of the country; one that will add a complete collection of Pringle's Mexican plants to its already excellent representation of the flora of that region and the Antillean islands. Mr. Patterson's herbarium is more or less contemporaneous with that of the late Mr. Bebb, which the museum secured some three years ago, and as Mr. Patterson made it his aim to secure a complete series of the species of North America, its addition to the collections of the museum will be of great value to botanical students and specialists in the west.

THE Royal Italian Institute of Military Geography ha thoroughly revised the old map of the region round about Vesuvius, issued by the institute in 1876, on the scale of 1/10,000. It has also completed a new plan in relief of the cone of Vesuvius which has been subject in recent times to considerable changes in its configuration owing to the repeated eruptions. Both map and plan have been prepared under the direction of Prof. Matteucci, who for years has made a study o Vesuvius. The correction of the map has been rendered necessary, not only by the eruptions, but also by the number of new roads and buildings.

THE discovery of a new gutta-percha is reported from Zanzibar. This substance is derived from a tree which grows principally at Dunga. When tapped with a knife, a white fluid exudes, which, when placed in boiling water, coagulates into a substance which in character bears a very striking resemblance to gutta-percha. As the material cools it becomes exceedingly hard, but while soft it can be moulded into any required shape. The fruit of the tree resembles a peach in shape, but grows to the size of a small melon. Experts have experimented with this new product to see if it in any way possesses the qualities of gutta-percha, and although it is not expected to prove equal to the genuine article, it is considered that it will be quite suitable for some purposes for which gutta-percha is at present utilised, and it will thus become a marketable article. It is said to abound in Zanzibar, and will be a very cheap product.

WRITING to the *British Medical Journal* on the subject of "Mosquitoes and Malaria," Mr. H. J. Elwes, F.R.S., says:—"The connection between mosquitoes and malaria seems to be now so clearly proved that some experiments should be undertaken by the Indian Medical Department to find out under what conditions mosquitoes do not produce malaria. Some years ago when on a hunting expedition in a very malarious district in the Bhotan Terai, I succeeded in escaping malaria by keeping within mosquito curtains till after sunrise, and getting into them again as soon as possible after dark, smoking freely at the same time within the curtains of my camp bed. Two out of the four Europeans of my party, and nearly all the natives who did not take these precautions, suffered so severely from malaria that our camp was unable to march after three weeks in the district. I may mention that it was then observed by experienced officers that from fourteen to eighteen days was the time which elapsed between exposure to infection and the appearance of severe fever. But there are places in Eastern Bengal and no doubt elsewhere where mosquitoes are very numerous and annoying, which do not seem to be subject to severe malaria, and I remember that Dacca, the only place where I was kept from sleeping a whole night by mosquitoes, was looked on as a station free from severe malaria, and I certainly, though I had previously been suffering from fever in Assam, never had a touch of it there. The great importance of finding out as soon as possible what precautions should be enforced by those responsible for the health of soldiers and others who are obliged to live in malarious districts cannot be overrated."

IN his report on the work of the Government Laboratory, Dr. T. E. Thorpe refers to the examination of some ordinary writing ink which was submitted to him by the Stationery Office, on a complaint that it thickened excessively and clogged the pen, and, in illustration, a sample of the contents of the ink-wells in use in the particular public office was forwarded, together with a sample of the ink as supplied. It was found that after the deposition of the separated solid matter of the ink, collected from the ink-wells in use, the fluid portion had a specific gravity twice that of the ink supplied. In other words, the ink had been allowed to become concentrated by evaporation to practically double its original strength through the use of excessively large ink-wells and inattention to the supply. It is, of course, necessary that the ink supplied shall be capable of furnishing a record which may be relied upon as permanent. Ink made with tannin and iron salts has had the advantage of very extended and prolonged use, with the result that complete confidence is felt as to the permanence of writing, for which it is used. But ink of this character possesses the undoubted disadvantage that it rapidly thickens on exposure, and Dr. Thorpe points out that it is specially advisable that such ink should be used in ink-wells of small size which receive regular attention at short intervals.

IT may safely be said that as petrol stands to-day as the paramount means of propulsion for automobiles accommodating passengers and of a light character, so steam has forced its way (at least in this country) as the means adopted for heavy motor vehicles for road service, carrying a load varying from three to ten tons. In support of this argument, an interesting article is given in the *Engineering Magazine* for September, describing these heavier types of vehicles, and although all typical designs are mentioned in every case, not petrol, but steam, represents the power used. As can be well imagined, these heavier class of waggon have had many difficulties to overcome, and with the exception of one type, a ten ton steam motor waggon by Messrs. C. and A. Musker, of Liverpool, the general designs are practically the same. The Thorneycroft waggon is fully described and illustrated in its different applications, ranging from the tipping dust van to a steam delivery waggon, and provided with a "trailer," by which is meant a vehicle towed behind. The ratios of gearing between the engine and the driving axle are 10·1 and 17·7 to 1. On all ordinary gradients five or six tons can be taken, two of which are conveyed on the trailer. Several other waggons by different makers are illustrated, with their dimensions graphically stated. The chief differences lie in the position and type of the engine, the power transmitted to the driving wheels in different ways, various kinds of boilers and different working pressures employed, and slight external appearance. The "Musker," already referred to, is only in its experimental stage, its chief features being an efficient liquid fuel burner combined with a flash-type boiler built up of three cylindrical coils of strong steel tubes, and the flame circulating in the annular space between them. All machinery is placed beneath the "body," thus affording a larger loading area than any other vehicle. It remains to be seen, however, whether the advantage claimed will be realised; if so, and considering its great load capacity (ten tons), it is indeed an important step in this branch of engineering.

A REPORT on the geology of the West Moreton or Ipswich coal-field in Queensland, by Mr. W. E. Cameron, has been published at the Geological Survey Office, Brisbane. It is accompanied by an appendix on the economic value of Queensland coal by Mr. Robert Wilson. The Ipswich coal-field is estimated to cover an area of about 12,000 square miles, and the coal has been most extensively worked in the neighbourhood of the town of Ipswich, which is about twenty-five miles south-west of Brisbane. The strata are of Jura-Trias age, and they are a good deal folded and faulted. They yield workable coals from two to four feet and more in thickness. Experiments made on the Government steamer *Otter* by Mr. Wilson show that some varieties are very good and useful steaming coals; and that generally the coals of Queensland "are well able to hold their own with any others at present found in Australia." The report is illustrated by a detailed geological map on a scale of an inch to twenty chains, and also by a geological map of a large area on the scale of an inch to a mile.

THE third volume of the *Annales* of the French Meteorological Office, containing rainfall values and completing the observations for the year 1897 (see p. 490), has been published in a greatly reduced form. The daily rainfall values are given for three hundred stations only, instead of nine hundred, and the scale of the rainfall charts has also been reduced. The valuable series of monthly and annual summaries are given for all stations, as before.

IN the *Botanical Gazette* for August, Prof. D. G. Fairchild is enthusiastic as to the advantages presented by the Botanic Garden at Rio de Janeiro for the study of tropical botany, although at present no facilities are afforded for teaching or study. He regards Rio, with its fashionable suburb Petropolis, as the most picturesque city in South America. To any botanist who wishes to study tropical vegetation, Petropolis and the other suburbs of Rio will prove the most attractive place in the world. As compared with the mountains of Java or Sumatra, they are civilised, and have a much more salubrious climate and all the conveniences of modern civilised life. The south island of Hawaii or the South Pacific Islands have no such stretches of virgin forest, or such a flora or fauna; to explore Ceylon is hot and uncomfortable in comparison; and the mountains of Jamaica and Trinidad are uninhabited except by scattered planters. Prof. Fairchild reckons the hotel expenses at Petropolis as about two dollars *per diem*.

FREQUENT as earthquakes are in the Philippine Islands, those of the year 1897, being unusual both in number and in violence, form the subject of an important memoir by P. José Coronas, which we have just received from the Observatory of Manila. He estimates the total number of shocks at 307, occurring in 108 groups. No part of the archipelago was entirely free from earthquakes, though less than five were felt in Mindoro, Paragua and the central part of Luzon. In the north-east of Samar, where more than a hundred were felt, they were most frequent and most destructive. Full descriptions are given of the three most important earthquakes—those of Luzon, on August 15; Zamboanga, on September 21, with the accompanying sea-waves and long series of after-shocks; and Samar, on October 19–20. Four of these earthquakes were recorded at distant stations, both Shide and Edinburgh being more than 11,000 kms. from the origins. The mean velocities of the waves of the two principal Zamboanga earthquakes are estimated at 8·7 and 8·1 kms. per second along the surface, or 7·6 and 7·1 kms. per second along the chords.

DETERMINATIONS of the rate of increase of underground temperature, apart from their scientific interest, have an important practical application in fixing the limit of depth at which mining operations can be carried on successfully. In this connection a report has been lately issued by the Department of Mines of the Government of Victoria, dealing with observations of underground temperature at Bendigo, the author being Mr. James Stirling, Government Geologist. The rise of temperature of the rocks with the depth varies in different parts of the earth's surface, thus making it difficult in any mining district to determine what the rate of increase is without actual experiment. Thus, if we accepted the hitherto recognised formula for the Bendigo field of 1° Fahr. for every 60 feet in depth, we should have a temperature of 125° at the 3,500 feet level. The observations already made prove that this temperature is not reached. It has been asserted in some quarters that mining might extend to as great a depth as 10,000 feet, if the difficulties of haulage could be overcome; but when we consider the effect of compressing the air at such a depth (*i.e.* the compression caused by its own weight), it will be seen that ventilation under ordinary conditions would be practically unattainable. At a depth of 10,000 feet the ventilating current entering the shaft at, say, a temperature of 60° Fahr., would attain a temperature of 90° by its own weight, altogether apart from the additional heat acquired by contact of the air with the heated rock surfaces. It is possible, however, to imagine a limit of 5000 feet as a workable depth, although the present observations as to the normal rate of increase of temperature of the rocks at Bendigo—1° Fahr. for every 135 feet—suggest 4000 feet as a convenient practical limit to healthy working. Mr. Stirling's report is accompanied by charts illustrating the temperature and pressure gradients in No. 180 mine. In connection with the composition of the air, Mr. Stirling calls attention to the very defective ventilation of many mines, and to the necessity of owners and directors of mines taking steps to remedy the existing evils.

IN NATURE, vol. lix. p. 133, we briefly referred to the very interesting investigations of MM. Hildebrandsson and Teisserenc de Bort into the history and present conditions of dynamical meteorology. Part ii. of this important work has now been issued, dealing generally with revolving storms, and the organisation of the international meteorological services, and particularly with the parts taken by Le Verrier, FitzRoy, and Buys Ballot, and reproducing specimens of the earliest reports and charts issued by each. Le Verrier seems to have been the first in Europe to conceive the idea of telegraphic weather forecasts, although, owing to inadequate support, he was the last of the three to introduce a regular working service. It is interesting to read, thirty-five years after the death of Admiral FitzRoy, the judgment of the eminent authors upon his work in this country, viz. that the criticism of his weather service was both severe and unjust, and Le Verrier's opinion is quoted that if he did not arrive at sufficiently practical results, probably on account of the limited area dealt with, no one else in his place could have done better. In another chapter, dealing with the fundamental works in the different countries between 1865 and 1872, the laborious investigations of Dr. Buchan occupy a prominent place. The publication of his remarkable memoirs and charts at this early epoch were of the highest importance in the development of dynamical meteorology, and the early researches made subsequently in other countries have been, to a great extent, simply verifications of his ideas. The Storm Atlas of Prof. Mohn, the present chief of the Norwegian Meteorological Service, the publications of the Meteorological Office, and the Synoptic Charts of the late Captain Hoffmeyer and of the Copenhagen and Hamburg institutes, are also specially referred to as having contributed greatly to the development of meteorological science.

THE remarkable colour-changes exhibited by a familiar prawn (*Hippolyte varians*) form the subject of an extremely interesting and most beautifully illustrated paper by Dr. Gamble and Mr. Keeble, which appears in the *Quarterly Journal of Microscopical Science* for September. The species in question may be met with commonly in the lower tidal pools along the shore, or may be obtained by trawling in deeper water. It has long been known that different individuals exhibit variations in colour ranging from one end of the spectrum to the other, and also that many specimens display a protective resemblance to the particular seaweeds on which they may be resting. It is now demonstrated that all the different colour-variations are capable of passing into one another, and the protective resemblances of individuals to their environment are most admirably displayed in the coloured plates with which the paper is illustrated. But this is not all. Twice during the twenty-four hours every specimen is living in deeper water than ordinary, and this includes a certain change in coloration to harmonise with the stronger or weaker light. But a much more important colour-change is induced by the daily alternation of light and darkness, and as the shades of evening approach every single individual of the species gradually loses its distinctive diurnal hue and becomes of a full transparent azure blue. The change is heralded by a reddish glow followed by a green tinge, which finally melts into the azure. And it is not a little remarkable that the day-and-night change has been so long established that it has become periodic and occurs whether the specimens are kept in perpetual darkness or *vice versâ*.

To the same journal Monsieur E. L. Bouvier communicates a supplemental paper on the results of his examination of the series of examples of Peripatus in the British Museum. He deals especially with the specimens described as *P. jamaicensis*, which are shown to include two perfectly distinct species.

OUR German contemporary, *Naturwissenschaftliche Wochenschrift*, of September 23, contains a long digest of Prof. G. Siebert's translation of Lydekker's "Geographical History of Mammals," which was published so long ago as 1897.

The additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Mrs. Woods and Mrs. Sassoon; a Plantain Squirrel (*Sciurus plantani*) from Java, a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Mrs. A. Jeffrey; a Ground Hornbill (*Bucorvus abyssinicus*), a Bell's Cinixys (*Cinixys belliana*) from West Africa, presented by Mr. Henry Strachan; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. W. R. Bryden; a Brazilian Tapir (*Tapirus americanus*), two Snowy Egrets (*Ardea candidissima*), six Ring-necked Lizards (*Tropidurus torquatus*), three Surinam Lizards (*Ameiva surinamensis*), a —— Lizard (*Crocodilurus lacertinus*), two Tuberculated Iguanas (*Iguana tuberculata*), six Giant Toads (*Bufo marinus*) from Para, presented by Captain A. Pam; a Vivacious Snake (*Tarbophis fallax*), European, presented by Mr. W. H. St. Quintin; a Spix's Macaw (*Cyanopsittacus spixi*) from Brazil, a Large Grieved Tortoise (*Podocnemis expansa*) from the Amazons, six Florida Tortoises (*Testudo polyphemus*) from North America, four Elegant Snakes (*Tropidonotus ordinatus infernalis*), four Couch's Snakes (*Tropidonotus ordinatus couchi*) from California, deposited; a Bristly Ground Squirrel (*Xerus setosus*) from South Africa, a Pink-headed Duck (*Rhodonessa caryophyllacea*) from India, purchased.

## THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The Royal Photographic Society hold their annual exhibition this year in the New Gallery, Regent Street, instead of, as heretofore, at the Water Colour Society's Gallery in Pall Mall. The result of the change to the larger galleries is certainly a matter for congratulation, because the very restricted accommodation of previous years crowded out professional and trade work, and gave very little space indeed for the exhibition of scientific and technical photography. This year, if any branch of photography is not represented, it is because of other difficulties than want of space. The only notable omission that occurs to us is that of cinematography, and this is accounted for by the very stringent regulations now enforced making a practical demonstration impossible.

The pictorial section occupies about as much of the walls as usual, and the greater part of the remaining space is taken up by professional and trade work, and apparatus exhibits, many of which, however, are not entirely devoid of scientific interest. But upstairs, in the gallery that runs round the central hall, there will be found a very excellent collection of "scientific, technical and photomechanical exhibits."

The Royal Observatory, Greenwich, contribute some of their most recent work with the 30-inch reflector, the 26-inch Thompson photographic refractor and other instruments. The photograph of the great nebula in Orion, taken last December, appears to be especially noteworthy. Two plates of the planet Eros are shown. A photograph of ξ Ursæ Majoris, taken with the 28-inch equatorial, the object-glass being corrected for photography by the separation of the lenses and reversal of the crown lens, as proposed by Sir G. G. Stokes, testifies to the value of this method of correction. Examples of work with the occulting shutter and several recent eclipse photographs will be examined with interest. Among several other astronomical photographs may be mentioned a paper enlargement of very considerable dimensions of the transit of Venus in 1882, by Prof. David P. Todd, and a series of photographs by the Rev. John M. Bacon illustrating his balloon ascent to search for the Leonids last November.

There are several contributions of photomicrographs. As examples of skill in this direction, the series by Mr. E. M. Nelson, of diatoms, exhibited by the Royal Microscopical Society, will probably attract the most attention. The natural history and biological photographs of all kinds are too numerous to refer to in detail. As notable illustrations of the value of a series of photographs illustrating biological changes, the sixteen lantern slides, by Mr. Martin F. Woodward, from his photomicrographs, showing the fertilisation and segmentation of the egg of *Ascaris megalocephala*, and a frame of photographs, by Mr. Edgar Scamell, showing the different stages in the growth of a nasturtium, will well repay careful study. The photographs in the latter series are so numerous that they would almost serve to illustrate the growth of the plant as a "living picture" by means of a cinematograph. It is very usual to slow down a rapid movement that its details may be recognised, and there is doubtless much to be learnt from the representation in a few seconds of changes that naturally require days or even weeks for their completion.

The applications of photography in many other directions are well illustrated. The automatic recording of the variations of scientific instruments, spectroscopic work, surveying, mining, engineering, the production of metal reliefs, are a few of the subjects that occur to us. Dr. W. J. Russell shows prints to illustrate the photographic activity of the radiations from "the metals radium and polonium," and also from uranium salts, which he finds do not lose any of their activity by keeping them for three years in the dark.

Photography itself, as distinguished from its applications, has received considerable attention, and we would point out that if exhibits of this character could be kept together in future exhibitions, it would much facilitate their study. A print from the enlargement (four thousand diameters), by Dr. Neuhauss, of a section of a film of a Lippmann interference photograph, copies of which have already been seen here, is exhibited by the doctor himself, and shows very clearly that the silver is deposited in layers, as the theory of the process indicates. Several examples of the Lippmann process may be seen in another part of the exhibition. An interesting demonstration of the possible range of exposure is given by the Kodak Company. They show seven negatives exposed under the same conditions, but for periods of from one to fifty, all of which were developed for the same length of time in the same developer. The longer the exposure the denser the negative, but the prints from them are scarcely distinguishable from one another. They show clearly that a small variation in exposure, or even none at all, will serve for very different subjects if negatives of various densities are not objected to.

Mr. Thomas Manly, the inventor of the "Ozotype" process of pigment printing, shows some examples of his method, one of which was exposed and washed thirteen months before the pigment was applied to it, proving that the power of the exposed bichromated paper to render gelatine insoluble and so fix the pigment does not sensibly change by keeping it. The process which in this country has hitherto been associated with Prof. Joly's name is illustrated by the Colour-photo Company of Chicago, and called the "McDonough-Joly process," referring to Mr. McDonough, who worked out the method in America simultaneously with Dr. Joly. They show that there is still room for improvement in the ruling of the triple coloured lines, and also in the nearer approximation of the photographic plate and the coloured screen. By looking at various angles across the ruling, the colour of the different parts of many of the pictures alternate between green, red and blue. This, we take it, is due to the distance between the colour screen and the photographic plate. Mr. Sanger Shepherd shows some striking examples of his triple film three-colour photographs.

The most notable novelty in apparatus is the "panoram kodak," for which the Kodak Company have been awarded a medal. All forms of projection have their advantages and their disadvantages. By adopting the cylindric or panoramic perspective, many subjects are possible for photography that could not be rendered by the plane perspective given by the ordinary fixed lens and plate. The arrangements necessary for a rotating lens have invariably been costly and heavy, and the Kodak Company have made quite a new departure in cameras in designing one that is light and cheap, and rapid enough in action to serve as a hand camera. The sample shown is called the "No 1 Panoram Kodak," from which we suppose that larger cameras of the same pattern will be issued in due course. It gives a picture seven inches long with a lens of about three and a half inches focal length. Film is used, and the drawing of it over the curved guides, to bring a new piece into position, is no more difficult than changing the film in any of the other kodaks. It has no shutter as usually understood, but the lens with its cone behind it swings beyond the sensitive surface and past a little flap, so that in its position of rest light cannot pass through the lens to the film. The apparatus is very ingeniously constructed, simple and effective.

There are many other exhibits of technical interest that might be noticed in detail, particularly, perhaps, photographs of living creatures of all kinds; but to enumerate them would be to reproduce a considerable portion of the catalogue. Many are evidence of the great skill and perseverance of the exhibitors. Some fine examples of photogravure show this process at its best. Some photogravures in colour, by Messrs. Ignatz Herbst and Theodore Reichs, show what can be done by a single printing after the various colours have been applied to the plate by the hand of one or more artists.

The exhibition is open daily until November 3.

---

## THE INTERNATIONAL GEOLOGICAL CONGRESS.

THE eighth International Geological Congress was held this year in France. The work of the Congress consisted of papers read at the meetings at Paris, which were followed by discussions, and by excursions into different parts of the country, conducted by French geologists.

The meetings of the Congress took place from August 10–27 at the Palais des Congrès, within the enclosure of the International Exhibition.

The inauguration was held on Friday, August 16, under the presidency of M. Leygues, Minister of Public Instruction and the Fine Arts. M. Karpinsky, president of the last session of the Congress at St. Petersburg, gave an address; he then read the following list of the members of the Committee, proposed by the Council:—Ex-presidents, MM. Capellini and Karpinsky. President, M. Albert Gaudry. General secretary, M. Charles Barrois. Vice-presidents—Germany: MM. H. Credner, Lepsius, Schmeisser, Zirkel, von Zittel. Austria and Hungary: MM. Böckh, Mojsisovics of Mojsvar, Tietze. Belgium: MM. Mourlon, Renard. Bulgaria: M. Zlatarski. Canada: Dr. Frank Adams. United States: Messrs. Hague, Osborn, Stevenson. France: MM. Michel-Lévy, Marcel Bertrand. Great Britain: Sir Archibald Geikie, Sir John Evans. India: Dr. Blanford. Italy: MM. Cocchi, Mattirolo. Japan: M. Kochibe. Mexico: M. Aguiléra. Norway: Dr. Brögger. The Netherlands: M. Martin. Portugal: MM. Choffat, Mendés-Guerreiro. Roumania: M. G. Stéfanescu. Russia: MM. Loewinson-Lessing, A. P. Pavlow, Sederholm, Tschernyschew. Sweden: M. Högbom. Switzerland: MM. Baltzer, C. Schmidt. Secretaries: MM. Zimmermann, W. Pavlow, von Arthaber, Gäbert, Crema, Cayeux, Thévenin, Thomas. Treasurer: M. Léon Carez. This list was voted with applause.

M. Albert Gaudry, the new president, then read the inaugural address. In the warmest terms the eminent geologist welcomed the assembly of scientific men who had come from all parts of the world, and then proposed that they should rise to show honour to the memory of the learned geologists who had passed away since the last Congress. The president referred to the principal propositions submitted during the preceding sessions, and enumerated the four sections of the present Congress:—

I. Section of general and tectonic geology.
II. Section of stratigraphy and palæontology.
III. Section of mineralogy and petrography.
IV. Section of applied geology and hydrology.

M. Charles Barrois, general secretary, read his report on the work of the Committee of Organisation. M. Leygues, Minister of Public Instruction and the Fine Arts, welcomed the foreign members of the Congress in the name of the Government.

Section I. (General and Tectonic Geology). President: Sir Archibald Geikie.

Papers:—Presidential Address on international co-operation in geological investigation; *Chamberlin*, the assistance of the Congress in the fundamental investigations of geology; *J. Joly*, the geological age of the earth fixed by the amount of sodium in the sea; on the experiments relative to erosion in fresh water and salt water; order of the formation of silicates in igneous rocks; mechanical structure of marine sedimentation; *A. de Lapparent*, definition for each of the periods of the history of the globe, of the regions where by preference arguments should be sought on which the precise delimitation of the geological strata and substrata could be founded; *Munier-Chalmas*, Parisian Tertiary strata, delimitation of the Secondary and Tertiary formations; *Stanislas-Meunier*, phenomena of subterranean sedimentation; *Bleicher*, denudation of the Lorraine plateau and its results; *Richter*, reading of the report of the Commission on Glaciers; *H. F. Reid*, on the movements of glaciers; *Arctowski*, remarks relating to the former extent of glaciers in the land regions discovered by the Belgian Antarctic expedition; *Popovici-Hatzeg*, presentation of the new geological map of Roumania on the scale of 1/300,000; *Vorweg*, proposition tending to simplify the observation of the inclination and strike of the strata; *l'Abbé Parat*, geological observations in the caves of La Cure (Morvan).

Section II. (Stratigraphy and Palæontology). President: Dr. von Zittel. Discussion on the report of the International Commission on Stratigraphic Classification.

Papers:—*Scott*, fauna of Patagonia; *Raulin*, Tertiary districts of Aquitania; *C. Eg. Bertrand*, charbons gélosiques et charbons humiques; *Grand'Eury*, formation of coal-seams in the coal basins of Central France; *Lemière*, transformation of vegetables into fossil fuel; *Osborn*, progress of the methods of palæontology; relations between the mammal fauna and the Tertiary horizons of Europe and America; *E. Ficheur*, presentation of the third edition of the geological map of Algeria on the scale of 1/800,000; *Flamand*, on the geology of the south of Algeria and the regions of the Sahara; *Douvillé*, on the Jurassic formation of Madagascar; on the results of the exploration of M. de Morgan in Persia; *Zeiller*, fossil plants of Tonquin; *Malaise*, the Cambrian and Silurian of Belgium; *Dr. P. Œhlert*, on the reproduction of fossil types; *W. F. Hume*, the rift valleys of Sinaï; *T. Barrow* and *W. F. Hume*, on the geology of the eastern desert of Egypt.

Section III. (Mineralogy and Petrography). President: Dr. Zirkel. Honorary Presidents: MM. Rosenbusch and Fouqué.

M. Lacroix announced the views adopted by the International Commission of Petrography in its meetings of October 25 and 26, 1899.

The following proposals were adopted by the Assembly:—

(1) The names of the authors should always be given after the names of the rocks, as is the custom in zoology and botany.

(2) It is proposed to the Congress of 1900 to appoint an International Commission charged to publish the names of all new rocks with their descriptions as concisely as possible, with also their chemical analysis and, if necessary, a drawing representing their structure. This publication is to appear in the volume of the reports of the International Congresses.

(3) It is, above all, desirable to regulate the nomenclature of the eruptive rocks, where the want of unity is particularly felt. Different authors attribute a different sense and signification to one and the same name, while different terms are employed to designate the same rock, the same group of rocks, or the same structure. All the inconveniences of the present nomenclature can, and should be, avoided, at least for the large groups.

(4) The characteristics of the large groups, for example, of the families should be founded on the mineralogical composition, supported by the chemical composition and the structure.

(5) The large groups ought to be fixed from the present without disturbing the subsequent development of the classification, and the separation of these groups into subdivisions.

(6) It is desirable to designate the principal types of structure by special names.

(7) It is necessary to avoid the employment of the same term in different senses.

(8) One should avoid as much as possible the employment and introduction of different terms to designate the same notion, the same rock, or the same group of rocks.

(9) It is necessary to avoid as much as possible for new types of rocks the employment of pre-existing names, and assigning to them a new sense, or restricting or enlarging their meaning.

Dr. Zirkel was elected president of the Committee of Petrography.

Papers:—*Sacco*, attempt at a general classification of rocks; *Salomon*, attempts at a nomenclature of the metamorphic rocks; *Weinschenk*, on dynamo-metamorphism and piézo-crystallisation; on the formation of graphite; *Hague*, on the Tertiary volcanoes of the Absaroka Range; *Sabatini*, the present state of our knowledge of the volcanoes of Central Italy.

Section IV. (Applied Geology and Hydrology). President: M. Schmeisser.

Papers:—*Mourlon*, the new methods of Belgian geology; *Gosselet*, mineralisation of deep-seated waters; *Van der Veur*, on the enlargement of the kingdom of the Netherlands by the draining of the Zuyder Zee; *L. Fabre*, the plateaux of the Hautes-Pyrenees and the dunes of Gascony; *Van den Broeck*, the applications of geology; *Kunz*, progress of the production of precious stones in the United States; *Léon Janet*, utilisation and protection of sources of drinking water; *De Launay*, the teaching of practical geology; *A. de Richard*, origin of petroleum.

General meetings. Presentation of works:—*E. de Margerie* and *L. Raveneau*, cartography at the Universal Exhibition of 1900; *Louis Raveneau*, ninth annual geographical bibliography of the annals of geography, 1899. Presentation of the reports and proposals of general interest adopted by the Council; the Assembly adopted successively:—

(1) Report of the Committee of Geological Nomenclature, presented by M. Tschernyschew, with the benefit of the remarks made at the meeting of the Section.

(2) Report of the Committee of the Geological Map of Europe, by M. Capellini.

(3) Report of the Committee of Petrography, by Dr. Zirkel.

(4) Report of the Glacier Committee, by M. Richter.

(5) Proposal by Sir A. Geikie on international co-operation in geological investigations.

(6) Proposition by M. Œhlert on the reproduction of types.

M. Tietze proposed to the meeting, on the part of the Austro-Hungarian Government, to organise in three years a new Session of the International Geological Congress at Vienna. He informed them of the advanced state of the preparatory work for such a congress, and enumerated the many excursions which would be arranged for the members of the Congress.

The invitation of the Austro-Hungarian Government was unanimously accepted, and M. Tietze thanked the Congress for the warm reception given to his proposal.

Papers:—*Matthew*, on the most ancient Palæozoic fauna; *Walcott*, the pre-Cambrian fossiliferous formations; *Cayeux*, on the radiolaria and sponges of the pre-Cambrian rocks of Brittany; *Pavlow*, the Portlandian rocks of Russia compared with those of the Boulonnais; on some means which would contribute to the determination of the genetic classification of fossils; *Van den Broeck*, on the age of the deposits of the Iguanodons of Bernissart; *Guébhard*, disturbances and fractures of the folds in the Alps of France; *Stanislas-Meunier*, structure of the diluvium of the Seine; *Hull*, sub-oceanic terraces and valleys of the rivers of the western coast of Europe; *Hudleston*, the eastern shores of the Atlantic; *E. Martel*, on the recent discovery of large caverns and fissures.

During the Congress receptions were offered to its members, first by the Geological Society of France, at their new rooms in the Hôtel des Sociétés Savantes. The president of this society, M. A. de Lapparent, of the Institute, inaugurated this reception by an address, which was warmly applauded. M. and Mdme. Albert Gaudry invited the members of the Congress to their house to a most brilliant soirée. Prince Roland Bonaparte received at his hotel the united members of the Geological and Anthropological Congresses, who were also received together by the Municipal Council at the Hôtel de Ville of Paris.

The Committee of Organisation offered a most brilliant banquet at the Hôtel du Palais d'Orsay; the addresses of M. Albert Gaudry, Sir Archibald Geikie, and MM. Tietze, Credner and de Lapparent were warmly applauded. Finally, cards for a reception at the Elysée, and tickets for the National Theatre, were placed at the disposal of the president by the Minister of Public Instruction and the Fine Arts, for distribution among the foreign members. Visits were arranged by the aid of the Committee, to the International Exhibition, the National collections of geology and mineralogy, to the Museum of Natural History, to the Sorbonne, and to the School of Mines.

The excursions of the Congress were well attended. The programme submitted to the geologists of the whole world was of the most tempting description. A pocket-guide, prepared by the united efforts of the French geologists, gave in several numbers a complete account of the geology of France.

In order to allow every one to take part in the greatest number of excursions, they were divided into three periods: before, during, and after the Congress.

(1) Excursions before the Congress: Ardennes, conducted by M. Gosselet; Gironde, by M. Fallot; Touraine, by M. G. Dollfus; Pyrenees (crystalline rocks), by M. Lacroix; Aquitania (Charente et Dordogne), by M. Glangeaud; Turonian of Touraine and Cenomanian of Le Mans, by M. de Grossouvre; Mayenne, by M. D. P. Œhlert; Brittany, by M. Barrois.

(2) Excursions during the Congress: Tertiary basin of Paris, MM. Munier-Chalmas, Léon Janet, Stanislas-Meunier and G. Dollfus.

(3) Excursions after the Congress: Boulonnais and Normandy, MM. Gosselet, Munier-Chalmas, Pellat, Rigaux, Bigot, Cayeux; Central Rocks, MM. Michel-Lévy, Marcellin Boule, Fabre; Coal-basin of Central France, MM. Fayol, Grand'Eury; Tertiary basins of the Rhone; Secondary and Tertiary rocks of the Lower Alps, MM. Deperet, Haug; Alps of Dauphiny, MM. Marcel Bertrand, Kilian, Lory, Paquier, Sayn, Léenhardt, Termier; Picardy, MM. Gosselet, Cayeux, Ladrière; Range of the Black Mountains, M. Bergeron; Pyrenees (sedimentary deposits), M. L. Carez; Lower Provence, MM. Marcel Bertrand, Vasseur, Zürcher.

These excursions, beginning on August 3, ended on October 2, and have had therefore a duration of three months.

The next meeting of the International Geological Congress will be held at Vienna in 1903. L. GENTIL.

## FORTHCOMING BOOKS OF SCIENCE.

MR. F. ALCAN (Paris) announces:—"De l'Infection en chirurgie d'armée. Evolution des Blessures de Guerre," by Dr. Nimier; and a new edition of volume i. of "Manuel d'Histologie Pathologique," by Profs. Cornil and Ranvier.

The Australian Book Company (of West Smithfield) announce:—"The Geology of Sydney and the Blue Mountains; A Popular Introduction to the Study of Australian Geology," by Rev. J. Milne Curran.

The announcements of Messrs. Baillière, Tindall and Cox include:—"The Hair in Health and Disease," by Dr. David Walsh; "Infantile Syphilis," by Dr. G. Carpenter; "Microscopy of the Starches," by Prof. Hugh Galt; "Standards of Foods and Drugs," by C. G. Moor; and new editions of Rose and Carless's "Manual of Surgery," Stewart's "Manual of Physiology," Walsh's "Röntgen Rays in Medical Work," Himes's "Guide to Public Health Acts," Hutchinson's "Aids to Ophthalmic Surgery and Medicine," Sparke's "Artiolic Anatomy of Man," Dennis's "Second-Grade Perspective."

Mr. Batsford promises:—"Waterworks Distribution," by J. A. McPherson, and "Sanitary Engineering," by Colonel Moore.

Messrs. Bemrose and Sons, Ltd., call attention to:—"Decimal Calculator and Multiplier," by C. Barker; and a new edition of "The Scientific Angler," by D. Foster.

Messrs. A. and C. Black will publish:—"The Human Ear: its Identification and Physiognomy," by Miriam A. Ellis; "Introduction to the Study of Physics," by A. F. Walden and J. J. Manley; vol. i. "General Physical Measurements—a Textbook of Zoology," by Dr. Otto Schmeil, translated R. Rosenstock; part iii. "Invertebrates."

Messrs. W. Blackwood and Son's list includes:—"Khurasan and Sistan," by Lieut.-Colonel C. E. Yate, illustrated; "The Sovereignty of the Sea," by Dr. T. Wemyss Fulton, illustrated; "A Manual of Classical Geography," by John L. Myres; "Physical Maps for the Use of History Students, (Greece, British Isles)" by Bernhard V. Darbishire; "Exercises in Geometry," by J. A. Third.

In the Cambridge University Press's list we notice:—"Scientific Papers," by Lord Rayleigh, F.R.S., vol. ii.; "Scientific Papers," by the late Dr. John Hopkinson, F.R.S., 2 vols.; "Scientific Papers," by Prof. Osborne Reynolds, F.R.S., vol. ii.; "The Scientific Papers of John Couch Adams," vol. ii., edited by Prof. W. G. Adams and R. A.

Sampson; "Lectures on the Lunar Theory," by John Couch Adams, from his collected Papers, edited by R. A. Sampson; "A Treatise on Spherical Astronomy," by Prof. Sir Robert S. Ball, F.R.S.; "A Treatise on Geometrical Optics," by R. A. Herman; "Advanced Exercises in Practical Physics," by Prof. Arthur Schuster, F.R.S., and Dr. Charles Lees; "The Prevention of Valvular Disease of the Heart," by Dr. Richard Caton; "Zoological Results based on material from New Britain, New Guinea, Loyalty Islands, and Elsewhere," collected during the years 1895, 1896 and 1897, by Dr. Arthur Willey. Part v., an account of the Entozoa, by A. E. Shipley; of the Nemertina, by R. C. Punnett; the development of the Robber Crab (*Birgus*), by L. A. Borradaile; new genera and species of Entromostraca, by the Rev. T. R. R. Stebbing, F.R.S.; anatomy of *Neohelia porcellana* (Moseley), by Edith M. Pratt, illustrated. "Fauna Hawaiiensis," or the Zoology of the Sandwich Islands: being results of the explorations instituted by the Joint Committee appointed by the Royal Society of London for promoting Natural Knowledge and the British Association for the Advancement of Science, and carried on with the assistance of those bodies and of the trustees of the Bernice Pauahi Bishop Museum, edited by Dr. David Sharp, F.R.S., vol. ii., part v. Arachnida, by Mons. Eugène Simon; Crustacea, Isopoda, by M. Adrien Dollfus; Amphipoda, by Rev. T. R. R. Stebbing, F.R.S.; (Cambridge Natural Science Manuals—Biological Series).—"Zoology," by Prof. E.W. MacBride and A. E. Shipley; "Fossil Plants; a Manual for Students of Botany and Geology," by A. C. Seward, F.R.S. In 2 vols. Vol. ii. (Physical Series)—"Electricity and Magnetism," by R. T. Glazebrook, F.R.S. (The Cambridge Series for Schools and Training Colleges)—"The Teacher's Manual of School Hygiene," by E. W. Hope and Edgar Browne; "An Introduction to Logic," by W. E. Johnson; "Euclid; Books I.-III., with Simple Exercises," by R. T. Wright; "An Introduction to Physiography," by W. N. Shaw, F.R.S.; "A New Primer of Astronomy," by Prof. Sir Robert S. Ball, F.R.S.; "A New Primer of Mechanics," by Prof. L. R. Wilberforce; "A New Primer of Physics," by the same author; "A New Primer of Physiology," by Dr. Alex. Hill; "A Brief History of Geographical Discovery since 1400," by Dr. F. H. H. Guillemard. (Pitt Press Mathematical Series)—"The Elements of Hydrostatics," by Prof. S. L. Loney.

Messrs. Carré and Naud (Paris) announce:—"Les Terres rares," by A. Job; "Les Nouveaux gaz," by Raveau; "Les sucres et leurs principaux dérivés," by Prof. L. Maquenne; "Essais du Commerce et de l'Industrie," by Cuniasse et Zwilling; "Chimie des matières colorantes," by Rudolf Nietzki, translated by C. Favre and Vaucher; "La Chimie photographique," by Namias Rodolf, translated by Jaquez; "La Vinification dans les pays chauds," by Dugast; "La Pratique industrielle des courants alternatifs," by Chevrier; "Microbiologie de la distillerie (Ferments, Microbes)," by Levy.

Messrs. Cassell and Co., Ltd., give notice of:—"Our Bird Friends," by R. Kearton, illustrated; "Cyclopædia of Mechanics," edited by P. N. Hasluck; "Practical Gas-Fitting and Practical Draughtsmen's Work," edited by P. N. Hasluck; "A Practical Method of Teaching Geography," by J. H. Overton, part ii.

Messrs. Chapman and Hall, Ltd., announce a new edition of "What is Heat? a Peep into Nature's most Hidden Secrets," by Frederick Hovenden, illustrated.

The list of Messrs. J. and A. Churchill includes:—"A Treatise on Physics," by Prof. A. Gray, F.R.S., in three parts, illustrated; and new editions of Notter, Firth and Horrocks's "Hygiene," and "Carpenter's Microscope and its Revelations," edited by Rev. Dr. W. H. Dallinger, F.R.S., illustrated.

Messrs. T. and T. Clark (Edinburgh) will publish:—"The Herschells," by James Sime.

In the list of Messrs. Archibald Constable and Co., Ltd., we notice "Through Siberia," by J. Stadling, edited by Dr. F. H. H. Guillemard, illustrated; "Across and About the Black Republic of Hayti," by Hesketh Prichard; "Travels in the East of Nicholas II., 1890-1," written by Prince E. Ookhtomsky, and translated by Robert Goodlet, edited by Sir George Birdwood, vol. ii.; "Motor Vehicles and Motors," by W. W. Beaumont, illustrated; "Modern Astronomy," by Prof. H. H. Turner, F.R.S., illustrated: "Practical Electro-Chemistry," by B. Blount, illustrated.

Messrs. Dent and Co. announce:—"Birds that come to our Houses and Gardens," by the Rev. H. D. Astley, illustrated; White's "Natural History of Selborne"; "Modern Chemistry," 2 vols., by Prof. Ramsay, F.R.S.; "Plants, their Structure and Life," by Dr. Dennert; "Primitive Man," by Dr. Homes; "First Aid to the Injured," by Dr. Drinkwater.

Messrs. Duckworth and Co. call attention to:—"Problems of Evolution," by F. W. Headley.

Mr. Wilhelm Engelmann (Leipzig) announces:—"Pompeji in Leben und Kunst," von A. Mau; "Die Rohstoffe des Pflanzenreichs. Versuch einer technischen Rohstofflehre. 2. Gänzlich umgearbeitete und erweiterte Auflage," I. Band, von J. Wiesner (Wien); "Monographien afrikanischer Pflanzenfamilien und -Gattungen," herausgegeben von A. Engler. V. R. Schumann, *Sterculiaceae africanae*; A. de Bary's "Vorlesungen über Bakterien." Dritte Auflage, durchgesehen und teilweise neu bearbeitet von W. Migula; "Hoffmann v. Fallersleben, Unsere volkstündichen Lieder." Vierte Auflage, herausgegeben und neu bearbeitet von Karl Hermann Prahl; "Die Assanierung von Paris" (Assanierung der Städte in Einzeldarstellungen, I. Band, Heft 1), von Dr. Th. Weyl; "Physikalisch-chemische Propaedeutik, unter besonderer Berücksichtigung der medizinischen Wissenschaften und mit historischen und biographischen Angaben," I. Band, von Prof. H. Griesbach.

Messrs. R. A. Everett and Co. give notice of:—"The Veterinary Manual for Horse Owners," by Frank T. Barton, illustrated; "The Stable Key, or Stud and Stable Studies," by Captain W. A. Kerr, V.C., illustrated.

The announcements of Messrs. C. Griffin and Co., Ltd., include:—"Central Electrical Stations," by C. H. Wordingham, illustrated; "The Metallurgy of Steel," by F. W. Harbord, illustrated; "A Dictionary of Dyestuffs," by C. Rawson, W. M. Gardner and W. F. Laycock; "A Dictionary of Textile Fibres," by W. J. Hannan, illustrated; "Pernicious Anæmia," by Dr. William Hunter; "The Construction and Maintenance of Vessels built of Steel," by T. Walton, illustrated; and new editions of "A Short Manual of Inorganic Chemistry," by Dr. A. Dupré, F.R.S., and Dr. Wilson Hake; "Tables and Data for the use of Analysts, Chemical Manufacturers and Scientific Chemists," by Prof. J. Castell Evans; and "Ore and Stone Mining," by Prof. C. Le Neve Foster, F.R.S., illustrated.

Messrs. Gurney and Jackson give notice of:—"The Birds of Ireland," by Richard J. Ussher and Robert Warren, illustrated; and a new edition of "Lunge's Coal-tar and Ammonia."

Mr. W. Heinemann's list includes:—"The Regions of the World, 1900," a series of twelve volumes descriptive of the physical environment of the nations, with maps by J. G. Bartholomew, edited by H. J. Mackinder, illustrated; vol. i. "Britain and the British Seas," by the editor; vol. ii. "Western Europe and the Mediterranean," by Élisée Reclus; vol. iii. "Central Europe," by Dr. Joseph Partsch; vol. iv. "Scandinavia and the Arctic Region," by Sir Clements R. Markham; vol. v. "the Russian Empire," by Prince Kropotkin; vol. vi. "The Near East," by D. G. Hogarth; vol. vii. "Africa," by Dr. J. Scott Keltie; vol. viii. "India," by Col. Sir T. Holdich; vol. ix. "The Far East," by Archibald Little; vol. x. "North America," by Prof. Israel C. Russell; vol. xi. "South America," by Dr. John C. Branner; vol. xii. "Australasia and Antarctica," by Dr. H. O. Forbes; "The Life of William Cotton Oswell," by his son, W. E. Oswell, illustrated; "The First Ascent of Mount Kenya," by H. J. Mackinder, illustrated; "Mount Orin and Beyond," by Archibald Little: "Nature's Garden: An Aid to Knowledge of Wild Flowers and their Insect Visitors," by Neltje Blanchan, illustrated; "Pompei: The City, its Life and Art," by Pierre Gusman. Translated by Florence Simmonds and M. Jourdain, illustrated.

Messrs. Hodder and Stoughton will issue in their "Self Educator" series:—"Botany," by R. S. Wishart; "Chemistry," by J. Knight.

Messrs. Hutchinson and Co. announce:—"The Living Races of Mankind," by Rev. H. N. Hutchinson, Prof. J. W. Gregory, and R. Lydekker, F.R.S., illustrated; "Disciples of Aesculapius, Biographies of Leaders of Medicine," by the late Sir Benjamin Ward Richardson, F.R.S., with a biography by his daughter, Mrs. George Martin, in 2 vols., with portraits and illustrations.

In the list of Messrs. Isbister and Co. Ltd., we notice:—"By Land and Sky," by Rev. J. M. Bacon.

The announcements of Messrs. Longmans and Co. include:—"Armenia: Travels and Studies," by H. F. B. Lynch. 2 vols. illustrated; "Diseases of the Anus and Rectum," by D. H.

Goodsall and W. Ernest Miles, two parts, illustrated; "Living Anatomy," by Cecil L. Burns and Dr. Robert J. Colenso, 40 plates, with descriptive letterpress; "Essays in Illustration of the action of Astral Gravitation in Natural Phenomena," by William Leighton Jordan; "A Practical Guide to Garden Plants," by John Weathers, illustrated; "Human Personality, and its Survival of Bodily Death," by Frederic W. H. Myers, 2 vols.

In the list of Messrs. Sampson Low and Co., Ltd., we observe:—"Golden Tips, a Description of Ceylon and its Great Tea Industry," by H. W. Cave; "The Inhabitants of the Philippines," by Frederic H. Sawyer, illustrated; "Lepcha Land, or Six Weeks in the Sikhim Himalayas," by Florence Donaldson, illustrated; "Textile Machinery, Recent Improvements," by E. A. Posselt, part ii.; and a new edition of "On the Manufacture of Vinegar, Cider and Fruit Wines, &c.," by W. T. Brannt.

The science list of Messrs. Macmillan and Co., Ltd., is:—"Life and Letters of Thomas Henry Huxley, F.R.S.," by Leonard Huxley, with portraits and illustrations, in 2 vols.; "Studies Scientific and Social," by Dr. Alfred R. Wallace, F.R.S., in 2 vols., vol. i. Scientific, vol. ii. Social, illustrated; "The Cambridge Natural History," vol. viii. Amphibia and Reptiles, by Dr. H. Gadow, F.R.S., illustrated; "The Scientific Memoirs of Thomas Henry Huxley," edited by Sir M. Foster, K.C.B., F.R.S., and Prof. E. Ray Lankester, F.R.S., in 4 vols., vol. iii.; "Dictionary of Philosophy and Psychology," edited by Prof. J. Mark Baldwin, in 3 vols.; "Cyclopedia of Horticulture," vols. iii. and iv., edited by Prof. L. H. Bailey, illustrated; "Botany, a Text-Book for Schools," by Prof. L. H. Bailey, illustrated; "The Principles of Vegetable-Gardening," by Prof. L. H. Bailey, illustrated; "Principles of Stock-breeding, the Application of Biological Laws to the Breeding of Domestic Animals (including Poultry), whether for 'Fancy' or Profit," by Prof. W. H. Brewer; "First Experiments in Psychology, a Manual of Elementary Laboratory Practice," by Prof. Edward B. Titchener, in 2 vols., vol. i. Qualitative Experiments, vol. ii. Quantitative Experiments; "Foundations of Knowledge," by Prof. Alexander T. O. McCosh; "School Geography," by Prof. R. S. Tarr, vol. iii. Europe, &c.; "The Principles of Mechanics," by Prof. Frederick Slate; "Design and Construction of Electric Power Plants," by Bion J. Arnold; "Elementary Electricity and Magnetism," by Prof. D. C. Jackson and Prof. J. P. Jackson, illustrated; "An Introduction to Celestial Mechanics," by Prof. Forest Ray Moulton; Surgical Technique, being a Handbook of and Operating Guide to all Operations on the Head, Neck, and Trunk," by Prof. Fr. von Esmarch and Dr. E. Kowalzig, translated by Prof. Ludwig H. Grau, edited by Prof. Nicholas Senn, illustrated; and new editions of "West African Studies," by Mary H. Kingsley; "The Golden Bough, a Study in Magic and Religion," by Dr. J. G. Frazer, 3 vols.; and "Modern Perspective, a Treatise upon the Principles and Practice of Plane and Cylindrical Perspective," by Prof. William R. Ware, with a portfolio of plates.

Messrs. Methuen and Co. give notice of:—"The Science of Hygiene," by W. C. C. Pakes, illustrated; "The Principles of Magnetism and Electricity: an Elementary Text-book," by P. L. Gray, illustrated.

Mr. Murray's announcements include:—"A Treatise on Medical Jurisprudence," by Dr. G. Vivian Poore; "The Life of Gilbert White," based on letters, journals, and other documents in the possession of the family and not hitherto published, by his great grand-nephew, Rashleigh Holt-White. 2 vols., illustrated; "The Birds of Siberia," by the late Henry Seebohm, with the author's latest corrections, edited by Dr. F. H. H. Guillemard, illustrated; "The Life of Sir John Fowler, Bart., K.C.M.G.," a record of engineering work, 1834–1898, by Thomas Mackay, illustrated; "The Natural History of Religion," based on the Gifford lectures delivered in Aberdeen in 1889–90 and 1890–91, by Prof. E. B. Tylor, F.R.S., illustrated; 'A Handy Book of Horticulture," by F. C. Hayes, illustrated; "Heredity," by Prof. J. Arthur Thomson, illustrated; a popular edition of "The Origin of Species by means of Natural Selection," by Charles Darwin, F.R.S., with a photogravure portrait of the author; and a new edition of "Scrambles Amongst the Alps in the Years 1860–69," including the history of the first ascent of the Matterhorn, by Edward Whymper, illustrated.

Messrs. George Newnes, Ltd., promise:—"The Story of Thought and Feeling" (an elementary book on Psychology), by F. Ryland; "The Story of Animal Life," by B. Lindsay; "In Nature's Workshop," by Grant Allen, illustrated.

Mr. J. C. Nimmo's list comprises:—"Babylonians and Assyrians, Excavations and Account of Decipherment of Inscriptions," by Prof. A. V. Hilprecht; "Syria and Palestine, Important Discoveries in Recent Years"; "Reminiscences of a Falconer," by Major C. H. Fisher; and new editions of "British Game Birds and Wild Fowl," by Dr. Beverley R. Morris; "Fern Growing, Fifty Years' Experience in Crossing and Cultivation, with a list of the most important varieties and a History of the Discovery of Multiple Parentage," by E. J. Lowe, F.R.S.; Rev. F. O. Morris's "A History of British Birds," 6 vols.; "A Natural History of the Nests and Eggs of British Birds"; "A History of British Butterflies"; "A Natural History of British Moths"; and "A Handbook of British Birds," by J. E. Harting.

Mr. D. Nutt's list contains:—"Mythology and Folktales, their Relation and Interpretation," by E. Sidney Hartland.

The announcements of the Oxford University Press include:—"The Structure and Life-History of the Harlequin Fly," by Prof. L. C. Miall, F.R.S., and A. R. Hammond; "A Textbook of Arithmetic," by Richard Hargreaves; "The 'Junior' Euclid," by S. W. Finn, Books III. and IV.

Mr. Y. J. Pentland announces:—"Text-book of Physiology," edited by Prof. Schäfer, F.R.S.; vol. ii. "Text-book of Medicine," edited by Dr. G. A. Gibson; "Text-book of Pharmacology and Therapeutics," edited by Dr. W. Hale White; and "Diseases of the Throat, Nose and Ear," by Dr. P. McBride.

Messrs. G. P. Putnam's Sons promise:—"Care of the Consumptive," by Dr. Charles Fox Gardiner; "Thomas Henry Huxley, a Sketch of his Life and Work," by P. Chalmers Mitchell, with portraits; "Medical and Surgical Nursing," edited by Dr. H. J. O'Brien; and a new edition of "Materia Medica for Nurses," by L. L. Dock.

The list of the Religious Tract Society includes:—"The Royal Observatory, Greenwich, a Glance at its History and Work," by E. Walter Maunder.

Mr. Grant Richards promises:—"Flame, Electricity, and the Camera," by George Iles, illustrated.

Messrs. Sands and Co. will add to their Library for Young Naturalists, edited by F. G. Aflalo, "The Animals of Africa," by H. A. Bryden, illustrated; "Types of British Plants," by C. S. Colman, illustrated.

Messrs. Walter Scott, Ltd., will add to their "Contemporary Science" Series:—"The Mediterranean Race," by Prof. Sergi, illustrated.

Messrs. Seeley and Co., Ltd., promise a new edition of "The Chemistry of Paints and Painting," by Prof. A. H. Church, F.R.S.

The list of the Society for Promoting Christian Knowledge contains:—"Among the Birds," by Florence Anna Fulcher; "Sounding the Ocean of Air," being six lectures delivered before the Lowell Institute of Boston in December, 1898, by A. Lawrence Rotch, illustrated.

Messrs. Swan Sonnenschein and Co., Ltd., call attention to:—Aristotle's "Psychology, including the Parva Naturalia," translated and edited with commentary and introduction by Prof. William A. Hammond; "A History of Contemporary Philosophy," by Dr. Max Heinze, translated by Prof. William Hammond; "Ethics," by Prof. W. Wundt, vol. iii.: The Principles of Morality and the Sphere of their Validity, translated by Prof. E. B. Titchener; "Physiological Psychology," by Prof. W. Wundt, translated by Prof. E. B. Titchener, 2 vols., illustrated; "Text-book of Palæontology for Zoological Students," by Theodore T. Groom, illustrated; "Text-book of Embryology: Invertebrates," by Dr. E. Korschelt and Dr. K. Heider, translated by Mrs. H. M. Bernard, and edited (with additions) by Martin J. Woodward, vol. iv., illustrated; "The Romance of the Earth," by Prof. A. W. Bickerton, illustrated; "Biological Types in the Vegetable Kingdom," by Wilfred Mark Webb; "Mammalia," by the Rev. H. A. Macpherson; "Birds' Eggs and Nests," by W. C. J. Ruskin Butterfield; "Inductive Geometry," by H. A. Nesbitt; and a new edition of "Handbook of Practical Botany, for the Botanical Laboratory and Private Student," by Prof. E. Strasburger, edited by Prof. W. Hillhouse, illustrated.

The following is the science list of the University Correspondence College Press:—"Algebra, The Tutorial, Part I., Elementary Course," by Rupert Deakin; "Arithmetic, The Tutorial," by W. P. Workman; "Building Construction (Science and Art)," by Brysson Cunningham; "Machine Construction, First Stage (Science and Art)," by J. Handsley Dales; "Mathematics, First Stage (Science and Art)"; "Physiography, Section One (Science and Art)," by Fabian Rosenberg; "Practical Plane and Solid Geometry, First Stage (Science and Art)," by G. F. Burn.

Mr. T. Fisher Unwin will add to his "Masters of Medicine" Series, "Thomas Sydenham," by J. F. Payne, and "Andreas Vesalius," by C. L. Taylor.

Messrs. Frederick Warne and Co. will issue new editions of:—"The Cattle Doctor," by Geo. Armatage; "Wayside and Woodland Blossoms, First and Second Series," by Edward Step.

Messrs. Wells Gardner, Darton and Co.'s list includes a new edition of "Playing at Botany," by Phœbe Allen.

Messrs. Whittaker and Co.'s announcements are:—"Periodic Classification and the Problem of Chemical Evolution," by George Rudorf; "Inspection of Railway Material," by G. R. Bodmer; "Electric Wiring Tables," by W. Perren Maycock; "Telephone System of the British Post Office," by T. E. Herbert; and "Horseless Road Locomotion," by A. R. Sennett.

## *MATHEMATICS AT THE BRITISH ASSOCIATION.*

THE mathematical communications to this year's meeting of the British Association were made on Monday, September 10, in one of the halls assigned to the Mathematical-Physical-Astronomical Section. Major P. A. MacMahon, F.R.S., took the chair.

The committee appointed in 1888 to calculate tables of certain mathematical functions opened the proceedings by presenting a report on their year's progress. The work on which they have for some time been engaged, namely, the preparation of a new "Canon Arithmeticus," is now almost completed. The calculations have been made by Lieut.-Colonel Allan Cunningham, who, in presenting the report, announced that the liberality of the British Association and of the Royal Society had enabled the committee to undertake the publication of the tables as a separate volume. Before the Association meets next year this will probably have been given to the world, and the committee, after an existence of thirteen years, will (unless some other work is found for it) cease to exist.

Another report was taken next—this time not of a committee, but of a single worker, Miss F. Hardcastle, of Cambridge, who was commissioned two years ago to prepare an account of "The present state of the theory of point-groups" for the Association. In the absence of Miss Hardcastle, one of the secretaries stated that a first instalment of the work is to be published in this year's annual report; this, however, will give only the general classification of the subject, and an account of those memoirs on the theory of elimination which are of importance in it. The greater part of Miss Hardcastle's report will not be ready until next year.

The chair was then taken by Prof. Forsyth, while Major MacMahon read a paper on "A property of the characteristic symbolic determinant of any $n$ quantics in $n$ variables." Let

$$a_{1x}^{\xi_1}, a_{2x}^{\xi_2}, \dots a_{nx}^{\xi_n}$$

be (in symbolic notation) any $n$ quantics in $m$ variables, and let

$$a_{1x}^{\xi_1} a_{2x}^{\xi_2} \dots a_{nx}^{\xi_n} = \dots + C_{\xi_1 \xi_2 \dots \xi_n} x_1^{\xi_1} x_2^{\xi_2} \dots x_n^{\xi_n} + \dots$$

Major MacMahon arrives at the remarkable result that

$$\Sigma\Sigma \dots \Sigma C_{\xi_1 \xi_2 \dots \xi_n}$$

(where the summation is extended over all positive integral values of $\xi_1, \xi_2, \dots \xi_n$) has the value $\frac{(-1)^n}{f(1)}$, where $f(\theta)$ is the characteristic determinant of the umbræ $a_{11}, a_{12}, \dots$

The next communication was made in French by Prof. Cyparissos Stephanos, of the University of Athens, "Sur les relations entre la géometrie projective et la mécanique." The fundamental thought of this paper may be explained as follows. Consider a system of forces in equilibrium. What geometrical transformations of space will transform this system into another system of forces also in equilibrium? Prof. Stephanos solves this problem, and finds that the only transformations which thus conserve equilibrium are those which, considered as performed on the Pluckerian co-ordinates of the forces, are linear and homogeneous. When the system of forces is coplanar, these transformations are homographies in the plane. This train of thought is of some importance in Graphical Statics.

Mr. H. S. Carslaw (Fellow of Emmanuel College, Cambridge) followed with a paper on "The use of multiple space in applied mathematics." The method of images, so powerful in electrostatical problems, can in its original form be applied only when the fundamental angles of the problem are submultiples of $\pi$. Prof. Sommerfeld pointed out a year or two ago that by introducing the idea of a branched space, analogous to the branched planes used in Riemann's Theory of Functions, the method of images can be freed from this limitation. Mr. Carslaw's work is an extension and development of this suggestion, which is applied by him to the solution of several of the standard problems of the potential theory.

Lieut.-Colonel Cunningham then gave some results obtained by himself and Mr. H. J. Woodall in the "Determination of successive high primes." As an example of a new process due to the authors, the factors of all numbers between 16 776 196, and 16 778 236 have been determined. 117 of the numbers in this series are found to be primes, a fact which led to some discussion on Riemann's work in the theory of prime numbers.

This was followed by a paper on "The construction of magic squares," by Dr. J. Willis, of Bradford, in which some new modes of formation were described and exemplified in diagrams. Major MacMahon then communicated two papers in succession. The first was entitled "The asyzygetic and perpetuant covariants of systems of binary quantics"; it was concerned with the extension, to a system containing any number of binary quantics, of the work which has already been done in connection with the semivariant forms of a single binary quantic.

In the second paper, "On the symbolism appropriate to the study of orthogonal and Boolian invariant systems which appertain to binary and other quantics," Major MacMahon explained a new and most remarkable method which he has discovered in the invariant theory, which promises to revolutionise the treatment of that subject. Previous writers have considered the invariant theory as consisting in the investigation of those forms associated with a quantic, which are invariant when the variables of the quantic are subjected to the general linear transformation. When the variables are subjected only to linear transformations of special types, such as the orthogonal and Boolian transformations, the family of invariant forms associated with a given quantic is, of course, much larger; but these special classes of transformations have hitherto been, comparatively speaking, ignored, as forming a tedious and outlying branch of the subject. Major MacMahon's discovery is a new symbolic method for obtaining the forms which are invariant for orthogonal and Boolian transformations, in the same way as Aronhold's symbolic method enables the investigator to obtain the forms which are invariant for the general linear transformation. Major MacMahon obtains six symbolic factors analogous to Aronhold's symbolic factors $a_x$ and $(ab)$, and the ordinary invariant-theory can be derived as a particular case of the new theory, by simply rejecting those forms which contain any one of a certain four of these factors.

A paper by Mr. A. B. Basset, F.R.S., in which the result that "a quintic curve cannot have more than 15 real points of inflexion"—an extension of a theorem of Zeuthen's on quartic curves—is obtained, was briefly communicated by the chairman; and a remarkably interesting session closed with two communications by Prof. J. D. Everett, F.R.S., "On Newton's contributions to central-difference interpolation," and "On a central-difference interpolation formula." In the former of these papers the author observed that certain formulæ in the calculus of finite differences, usually attributed to Stirling, were really known to Newton; in the second, a formula of interpolation was obtained which is less unsymmetrical than those generally given.

E. T. WHITTAKER.

## PHYSICS AT THE BRITISH ASSOCIATION.

THE interesting way in which Dr. Larmor, in his Presidential Address to Section A, touched on some of the problems of theoretical physics appears to have had a considerable influence on the subsequent proceedings of that section during the meeting at Bradford. At few recent meetings has the number of impromptu discussions of theoretical questions been so great, and even although these discussions may not always have been ended in the settlement of some question previously in dispute, they have provided in a way that only the Association meetings can, opportunities for exchanges of opinions so necessary in these days of specialisation, and so valued by those who have the advance of their subject at heart.

The large section room was well filled for the President's address. After a vote of thanks moved by Prof. FitzGerald and seconded by Principal Oliver Lodge had been carried, a large proportion of the audience left to hear the address of Prof. Perkin, the President of Section B, and the reading of papers commenced. In what follows they are given in order of subject and not of reading.

Dr. Trouton gave a short account of his experiments on the creeping of liquids, and on the surface tensions of mixtures. He has found that the tendency of certain liquids to creep up the sides of their containing vessels is due to such liquids being mixtures. The more volatile constituent creeps in advance of the other, and the action is stopped if evaporation is prevented. Zinc surfaces seem more favourable to the process than surfaces of other metals or of glass. The surface tensions of mixtures of liquids are as a rule less than the values calculated from the surface tensions and proportions of their constituents, while those of salt solutions increase with the number of gram equivalents of the salt present at a rate nearly independent of the nature of the salt, a fact to which Quincke was the first to draw attention.

Prof. G. H. Bryan, in a note on the partition of molecular energy, explained how, in his endeavour to build up irreversible thermal phenomena from reversible dynamics, he had been led to a novel method of investigating the mean distribution of energy amongst a number of particles moving in an external field having a potential. He found that two such particles do not follow Maxwell's law of partition of energy, and concluded that the law would not be followed in a general assemblage of particles. Prof. FitzGerald considered that two particles in an external field did not sufficiently represent the molecules of a gas, and suggested that if the case of three particles had been worked out, they would have been found to follow Maxwell's law. He hoped that physicists would accept that law as valid for gases till a system had been constructed for which it could be proved conclusively not to hold. Prof. Bryan, on the other hand, challenged physicists to construct a simple system of particles which *would* tend towards Maxwell's distribution of energy.

Dr. Larmor gave some results of his application of the principle of least action to the statistical dynamics of gas theory, as illustrated by meteor swarms and optical ray systems. He finds that if a swarm of meteors is moving under its own mutual attractions and conservative outside forces, and if from some point vectors be drawn equal and parallel to the velocities of the meteors, the product of the volume marked out by the ends of these vectors into the volume occupied by the meteors themselves will remain constant throughout the motion. If the mutual attractions are insensible, the product of the solid angle bounded by the velocity vectors into the square of the mean velocity of the swarm will remain constant. In optics this corresponds to the concentration in cross section of a beam being proportional to the solid angular divergence of the beam, into the square of the refractive index of the medium in which it is travelling. In the case of a gas where encounters between the particles may take place, the above distribution of particles and velocities is found to be a possible steady state.

The report of the Seismological Committee was presented by the secretary, Mr. Milne. During the past year he has analysed the records of the earthquakes which occurred during 1899, and has found that the earthquake wave takes about 110 minutes to travel from its origin to the opposite end of the earth's diameter, but whether it is propagated through the centre of the earth or as a surface wave cannot at present be decided. He suggests that earthquakes may be connected with the small changes of latitude known to occur, and that earthquake waves may have a disturbing effect on the timepieces of observatories. Messrs. Clement Reid and Horace Darwin are engaged in an attempt to detect movements at a geological fault owing to earthquakes.

The Committee on the sizes of pages of periodicals reported that it had succeeded in some cases in inducing societies publishing proceedings of exceptional sizes to conform to the rules the committee laid down in its 1895 report. It did not seek re-appointment.

A paper on the relation of radiation to temperature was contributed by Dr. Larmor. The late Prof. Balfour Stewart pointed out at the meeting of the Association in 1871 that if an enclosure at constant temperature contained a moving body at the same temperature, the radiation received from the body at a point in advance would, by Döppler's principle, differ from that received by a point behind the body. Dr. Larmor applies this principle to the case of a spherical enclosure shrinking in size, in which, therefore, the wave-lengths of all radiations will decrease as the radius. Further, there will be a pressure of the radiation on the inside surface of the sphere, which will require work to be performed during the shrinkage. This work is converted into radiation, and changes the temperature of the radiation inversely as the radius, and the energy of the radiation inversely as the fourth power of the radius. From this Stefan's law that radiation is proportional to the fourth power of the temperature follows; and further, the energy of radiation between $\lambda$ and $\lambda + d\lambda$ is of the form $\lambda^{-5}f(\lambda T).\delta\lambda$. Prof. FitzGerald pointed out the great simplification which Dr. Larmor had introduced into the treatment of the problem by the consideration of the radiation in the ether only, a method of which the legitimacy could not be doubted.

Dr. S. P. Langley sent over from America a chart of the infra red spectrum from ·7 to 5·3 $\mu$, obtained by the bolometric method described in his communication to the Association at Oxford in 1894. His bolometer is now arranged so that a difference of temperature of one-millionth of a degree centigrade is detected; and the whole operation of producing the charts is automatic. They show distinctly the variation of atmospheric absorption with the seasons, and may possibly, he thinks, lead to a new method of weather forecasting.

The Committee on Meteorological Photography reported that as the result of about 400 photographic observations of clouds made from two stations near Exeter, the following mean heights have been found:—Cirrus, 10,200; cirro-cumulus, 8600; cumulus top, 3000; base, 1300; strata-cumulus, 2200 metres. During the early part of the day the clouds rise, attain their maximum altitudes about 2 or 3 p.m., and fall during the afternoon and evening. The greatest altitudes are associated with thunderstorms and the lowest with cyclones.

The Committee on Solar Radiation reported that experiments had been made under the direction of Prof. Callendar, with a view to testing the modified copper-cube actinometer and reducing its records to an absolute scale. During the course of these experiments it has been found necessary to introduce further changes, and the instrument now used consists of a blackened copper disc provided with thermojunctions, suspended within a tubular water jacket around which a stream of water at constant temperature is maintained. The radiation to be measured passes down the tube and falls normally on the copper disc. This instrument has been tested by exposing it to the radiation from an electric lamp at a known distance, and has been found capable of giving consistent results for weak radiation, but the intensity of solar radiation is too great to permit the elementary theory of the instrument to be applied. It is, therefore, proposed at present to record only the *vertical* component of the radiation from sun and sky by means of the bolometric method described in the 1898 report. Two flat platinum thermometers, one bright and the other blackened, are placed horizontally side by side and exposed to the radiation from the sky. Their difference of temperature is automatically recorded, and is taken to be proportional to the radiation to which they are exposed. By means of an observation with an electric lamp at a fixed distance, the indications of the instrument can be converted into absolute measure.

Mr. A. S. Davies described a novel form of mercurial barometer, in which a fixed volume of the gas the pressure of which is to be determined, is compressed isothermally by a column of mercury of known length and the compression measured. The instrument consists of a glass bulb, from which a tube of small bore projects downwards, and ends in another bulb open to the air and containing a little mercury. When a reading is required, the instrument is inverted so that a column of mercury runs down the tube towards the first bulb and compresses the air in it. From the position taken up by the end of this column, when the compressed gas has cooled to its original temperature, the original pressure of the gas can, if the gas is dry, be found. In the instrument this pressure is read off on a scale alongside the tube. The air enclosed is dried by passage through a plug containing calcium chloride. The instrument is very compact and portable.

Mr. A. L. Rotch contributed a note on the use of kites for meteorological observations at Blue Hill Observatory, Mass. Observations with kites have been made up to 16,000 feet above sea level, and have been reduced and published in abstract in NATURE, July 12 and August 9.

Captain Campbell Hepworth exhibited and discussed some charts illustrating the weather of the North Atlantic Ocean during the winter of 1898-9. At sea this period was one of violent storms, while the weather in America was exceptionally cold, and in Europe very mild. Some of the cyclones crossed quickly from the American coast to the British Isles, while others—in particular the worst one in February—made slow progress. Much damage was done to shipping, and even powerful vessels, like the *Lucania* and the *Fürst Bismarck*, were unable to make headway, and arrived at their destinations several days late.

Mr. J. W. Thomas, in a communication on the physical effects of wind in towns and their influence upon ventilation, pointed out that the well-known effect of currents of air in diminishing the air pressure in vessels across the openings of which they passed, was generally neglected by writers on ventilation. A gusty wind, during its period of maximum velocity, reduces the air pressure in a room by the withdrawal of air through the chimney. When the wind lulls, the air passes down the chimney into the room, and the chimney "smokes."

Mr. J. Hopkinson gave an account of the rainfall of the northern counties of England. The means for the ten years ending 1890 are :—

Cumberland, 57·9 ; Westmoreland, 55·9 ; Derbyshire, 40·2 ; Lancashire, 38·3 ; Yorkshire, 33·4 ; Cheshire, 31·3 ; Northumberland, 31·0 ; Durham, 28·1 ; Nottinghamshire, 24·4 ; Lincolnshire, 24·3 inches per annum. These numbers show distinctly the effect of highlands in increasing the average rainfall.

Mr. G. E. Petavel described the apparatus he is using in his experiments on the explosive pressures of gases. He measures the maximum pressure attained in his explosion vessel by means of a piston which is forced out and makes a telephone contact if the pressure exceeds a certain value. By means of the compression of a cylinder he measures also the rate of change of the pressure. He finds that in the case of hydrogen and oxygen the maximum is about ten times the initial pressure, and that inert gases delay but do not greatly diminish the maximum pressure.

Mr. J. W. Gifford gave an account of a quartz-calcite lens he had designed, having the same focal length for wave-lengths 5607 and 2761, which he considers may be taken as the centres of the visual and photographic portions of the spectrum respectively.

Messrs. A. Dufton and W. M. Gardner exhibited at the Technical College an arrangement they had devised for the production of an artificial light of the same character as daylight. Such an artificial light has been much wanted by those engaged in dealing with coloured stuffs, and the practical demonstration given by the authors showed that they have successfully supplied this want. They use an enclosed arc lamp, and surround the translucent bulb of the lamp by a tank containing a solution of copper sulphate of the proper strength, or by a box with sides of glass of the same colour and the requisite thickness.

Mr. H. Ramage described his method of investigating correspondences between spectra. He takes wave frequency as abscissæ, and atomic weights of the elements whose spectra are to be compared as ordinates, and joins by lines the "corresponding" points of the various spectra. These lines are in general curved, and in the case of the components of a doublet their distance apart increases with the atomic weight. If the squares of the atomic weights are taken as ordinates, they become straight lines intersecting on the axis of wave frequency. He proposes, therefore, to introduce a term $a\mathrm{W}^2$, where $a$ is a constant, and W the atomic weight, into Rydberg's formula, which will thus become $n = n_0 - a\mathrm{W}^2 - \frac{\mathrm{N}_0}{(m-\mu)^2}$.

Mr. G. J. Burch exhibited an experiment on simultaneous contrast. One half of the slide of a stereoscope consists of blue and the other of red glass. By means of diffraction gratings in the eyepiece of the stereoscope, two spectra are produced which appear to cover two patches of black paper on the two glasses. Under these circumstances, that seen by the eye which looks at the red glass appears to lack red, the eye being partially blinded for red, the other for a similar reason lacks blue. In Mr. Burch's opinion these facts confirm the views of Thomas Young on colour contrast.

The Committee for improving the method of determining Magnetic Force on Board Ship reported that an instrument had been constructed according to the designs of Captain Creak, which gave promise of overcoming many of the difficulties met with in using Fox's circle.

The work of the Committee on Radiation in a Magnetic Field had been interrupted by the death of Mr. Preston, but the committee now proposed to issue copies of Preston's photographs showing how the various types of lines are affected by the magnetic field.

The Electrical Standards Committee reported that the standards had been removed to Kew, where an outbuilding had been fitted up for the temporary use of the committee of the National Physical Laboratory. The sub-committee on platinum thermometry has decided that platinum thermometers shall be constructed of a selected sample of platinum wire, and be used as standards for high temperature measurements. The selection of wire is still under the consideration of the committee. Arrangements have been made for the construction of a mercury resistance standard and an ampere balance. The Committee approves of the adoption of the names *Gauss* and *Maxwell* for the C.G.S. units of magnetic field and flux respectively.

Mr. R. S. Whipple gave an account of his improved standard resistance coils. Alongside the platinum-silver wire of the standard coil a second wire of platinum is wound. The difference of resistance of the two coils depends on their temperature, which may therefore be regulated to have any required value. Dr. R. T. Glazebrook pointed out that the method had been used by Messrs. Crompton in constructing their standard resistances.

Mr. E. H. Griffiths described the form of Wheatstone bridge he has devised for determining the freezing-points of dilute solutions by platinum thermometry. A platinum thermometer of about 18 ohms resistance placed in the solution, and another similar one in ice, form two of the arms of a Wheatstone bridge. The rest of the bridge is of platinum. The galvanometer is connected to the bridge by means of two sliders, each of which moves along a pair of platinum wires, one of the pair forming part of the bridge, and the other connected permanently to the galvanometer. The readings of these sliders for a balance determine the difference of temperature of the two thermometers. Using a Paschen galvanometer giving a deflection of 1 mm. on a scale 1 metre distant for a current of $10^{-12}$ ampere, Mr. Griffiths can determine temperature to one-millionth of a degree centigrade. Mr. R. Threlfall pointed out that although the temperature of the platinum wire of the thermometer could be determined to this degree of accuracy, the temperature of the solution could not. In reply to Dr. Glazebrook, Mr. Griffiths stated that the mercury contacts in Carey Foster's method introduced changes which prevented this high degree of accuracy being attained with it.

Prof. F. G. Baily described a lecture-room form of volt and ammeter which he had devised. By means of a series of resistance coils all contained in a small box, the deflections of a galvanometer of the d'Arsonval type are made to correspond to simple multiples or submultiples of a volt or an ampere.

Prof. W. B. Morton communicated some results he had obtained by applying J. J. Thomson's and Sommerfeld's solution of the propagation of an electric wave along a single wire, to the approximate solution of cases of several parallel wires, some of which may be returns, when the square of the ratio of the radii of the wires to their distances apart may be neglected. His results agree with the more complete investigations given by Mie in the June number of the *Annalen der Physik*.

A communication from Mr. S. H. Burbury on the vector potential of electric currents in a field where disturbances are propagated with finite velocity, was, in the absence of the author, taken as read. There are difficulties in the way of the usual definition of the vector potential due to electric currents when these currents are changing. These difficulties Mr. Burbury proposes to obviate by substituting in the definition, for the current at a given point at the given instant, the current which existed at that point $r/V$ seconds before, where $r$ is the distance of the point from that at which the vector potential is to be measured, and V is the velocity of propagation of an electric disturbance.

The communication which most attracted the attention of the members of the Association, and produced a great addition to the attendance at Section A, was that of Sir William H. Preece on wireless telephony. By a series of experiments carried out at Lock Ness, the Menai Straits, the Skerries and at Rathlin Island, he has shown conclusively that wireless telephony is a practical and commercial system. At the Skerries a line half a mile long terminated by earth plates placed in the sea, at a mean distance of nearly three miles from a similar wire three and a half miles long on the mainland, was quite sufficient to enable telephonic messages to be transmitted with the ordinary instruments. At Rathlin Island the wire is eight miles from the mainland and communication is readily maintained. Endeavours are to be made to extend the system to ships and there seems every probability of success.

Prof. G. F. FitzGerald, in a note on Crémieu's experiment, described the arrangement adopted by Mr. Crémieu and the negative result he had obtained, and contrasted them with the arrangement and result obtained by Rowland in his experiments on electric convection made in 1876. He considered that the discrepancy of the results of experiments, which appeared to have been carried out with great care, did not necessarily disprove our theory of electromagnetism, but rather signified that there was some action of a moving ion not hitherto included in our equations which was well worth investigating. Dr. J. Larmor pointed out that any want of symmetry of the revolving disc and fixed case in Crémieu's apparatus would tend to cause some part of the charge on the disc to remain stationary. Prof. A. Gray announced that he had already commenced work with a view to repeating both Rowland's and Crémieu's experiments with the same apparatus.

Prof. J. Chunder Bose gave an account of his work on the effect of electrical stimulus on inorganic and living substances. By measurements of conductivity he determines the magnitudes of the changes produced in the molecular structure of substances due to an electric stimulus. Taking time of exposure to stimulus, or time of recovery from effect of stimulus, as abscissæ, and change of conductivity as ordinates, he draws curves for numerous substances under varying conditions. He finds that the curves for organic and inorganic substances are similar. On this as a basis he has constructed an artificial retina, which has enabled him to explain many obscure phenomena of vision.

The Committee on Electrolysis and Electro-chemistry reported that the experiments on the freezing points of the solutions whose electrical conductivities had been found by Mr. Whetham were still in progress. Some experiments on the consumption of carbon anodes in electrolysis have been made by Mr. Skinner, who has found that the anion produced by electrolysis of any highly oxidised material consists partly of carbonic acid. The committee now lapses.

Prof. G. F. FitzGerald opened a joint discussion with the chemical section, on ions. While acknowledging that the dissociation theory of electrolysis had proved a useful hypothesis, he wished to draw attention to the fact that there were phenomena which it was incapable of explaining, and that dissociation itself had not been dynamically explained. Why should water dissociate a dissolved salt into its ions? where does the necessary energy come from? how can the dissociated ions wander about in the solvent without recombining? and why do some ions travel faster than others? seemed to him questions which the supporters of the theory had never satisfactorily answered. The recent work on conduction in gases seemed to render it necessary to restrict the term "ionisation" in future to the process of producing atoms differently electrified, and to introduce a new term "electronisation" for the production of conductivity by the motion of particles of apparent mass about 1/500 of that of a hydrogen atom. In gases conductivity was probably due to both causes, and in liquids to the former only. In the case of metals, he should like to ask, how thick was the layer of electricity on the surface? did the thickness of a thin metal plate alter its capacity? and would the electrons fly to the surface of a metal when it revolved? He thought the questions still open to discussion might be summarised as follows:—

(1) The cause and nature of ionisation.

(2) The source of the energy in dissociation in a liquid.

(3) The cause of the failure of the law of dissociation as the concentration increased.

(4) The reason for the different rates of migration of the ions.

(5) The nature of the double layers, or why different metals should attract electricity differently.

(6) Are the processes of ionisation the same in liquids and gases? and, if so, why?

(7) Do electrons gravitate, *i.e.* have they a material nucleus or not?

(8) Is magnetism due to rotation of the electrons?

Dr. Larmor, before calling on the chemists present for their remarks, pointed out that the large dielectric constant of water meant a large electric moment for the water molecule, and therefore a considerable separation of the positive and negative charges on the molecule. A molecule of dissolved salt might therefore readily come under the influence of one of these charges alone.

Prof. H. E. Armstrong stated that in the opinion of chemists the atoms were permanent and stable, and that the removal of 1/500 of the mass of a hydrogen atom along with its negative charge seemed to them impossible. He thought that the same process produced conductivity in gases which produced it in liquids; that in gases the vapour of water played the part of the water in electrolysis of a dissolved salt, and that in all cases it was necessary to form a "triplet" by the presence of a third substance, before any chemical or other action could result. This third substance was generally one having one of its constituents in an "unsatisfied" condition, like the oxygen in water or the nitrogen in ammonia, and in which there was in consequence a tendency towards "association" of molecules.

Mr. Whetham stated by letter that he did not think the difficulties of the dissociation theory were as great as they were represented. The ions might be free from each other but be connected with the molecules of the solvent.

Principal Oliver Lodge thought that although in a liquid the charges apparently travelled with the atoms, while in a gas the electrons appeared to be free, in neither case was conduction by means of molecular aggregates excluded. He considered metallic conduction the handing on of the electrons from one atom to another. He looked forward to an electrical theory of matter, in which the hydrogen atom would consist simply of 500 electrons without nuclei.

Mr. W. J. Pope pointed out that the dissociation theory only held up to concentrations of 5 per cent., and that there was a difficulty in the case of salts which on account of their asymmetry rotated the plane of polarisation of light.

Dr. H. C. Pocklington gave an account of his work on the radiation of a black body on the electro-magnetic theory. Assuming that the energy of the total radiation emitted by a black body at any temperature is the product of powers of the temperature $\theta$, the velocity of propagation of the radiation $v$, and the atomic charge Q, Dr. Pocklington finds by the theory of dimensions that the power of the temperature is 4, *i.e.* Stefan's law, and that the radiation between $\lambda$ and $\lambda+\delta\lambda$ is proportional to

$$\theta^4 \,.\, v \,.\, Q^{-6} \frac{d\lambda}{\lambda} \,.\; f\left(\frac{\theta\lambda}{Q^2}\right),$$

in agreement with Wien's law.

Mr. C. E. S. Phillips gave an account of his experiments on the apparent emission of kathode rays from an electrode at zero potential. He has found that the green flecks which make their appearance on the inner surface of a partially exhausted vacuum bulb when a discharge passes, are due to the emission from the kathode of jets of occluded gas, which continue even when the two electrodes of the bulb are both earth connected. These jets produce shadows of opaque bodies held in their path, and although their velocity is probably not greater than that of sound, they can cause the green fluorescence in the glass on which they impinge.

Mr. J. B. B. Burke communicated a paper on the phosphorescent glow in gases. He uses electrodeless tubes, and finds that the glow begins to appear at a pressure of ·7 mm., is a maximum at ·1, and disappears at ·02 mm. of mercury. It seems to be composed of two parts, one carrying the charge, the other uncharged, but capable of producing conductivity in those parts of the tube to which it penetrates. The conductivity effect is propagated quickly, but the glow appears to be propagated by diffusion along the tube. Prof. A. Smithells mentioned that his experiments on flame showed that the emission of light from the flame was in the same way independent of the conductivity of the flame.

At the close of the meeting of the section on Wednesday morning, September 12, votes of thanks to the president and secretaries were passed, and the section adjourned to Glasgow.

C. H. LEES.

---

## *ASTRONOMY AT THE BRITISH ASSOCIATION.*

ASTRONOMY this year constituted a distinct department of Section A, with its own chairman and secretaries, and a separate room was provided for the reading of papers on this subject. The new departure was sufficiently justified by the attendance at the meetings, and in future years, when the formation of the Department of Astronomy becomes more widely known, increased success may be confidently expected. The department met on Friday, September 7, and Tuesday, September 11, and altogether sixteen papers were read.

At Friday's meeting, after the chairman's address, three papers by Prof. Todd, relating to eclipse work, were read by one of the secretaries in the absence of the author. In one of these attention was called to the "application of the electric telegraph to the furtherance of eclipse research." In 1878, the idea first occurred to Prof. Todd to telegraph eastward in advance of the lunar shadow in order to enable the immediate verification of any possible discovery, as of an intramercurian planet, without waiting for another eclipse. The feasibility of the method was demonstrated in January 1889, and again more completely during the eclipse of May 28, 1900. At the station occupied by Mr. Douglas in Georgia, totality preceded the same phenomena in Tripoli, where Prof. Todd himself was observing, by 2h. 45m., and the outcome of the experiment was that, through the generous help afforded by the various telegraph companies, an account of the American observations was received by Prof. Todd more than two hours before totality occurred at Tripoli. Abundant time for special preparations to verify any important discovery was thus available.

In his second paper Prof. Todd dealt with a variety of methods of operating eclipse instruments automatically. The "mechanical system," as distinct from the pneumatic and electric arrangements which he had previously devised, was first tried during the recent eclipse. The instruments being set up on the roof of the British Consulate, gravity was utilised for the mechanical operation of slides and shutters. One hundred photographs were secured at Tripoli by seven instruments operated in this manner. Experience indicates that the gravity method is the best where the number of instruments is not great.

Another paper by Prof. Todd described the use of a wedge of yellow optical glass in giving correctly graduated exposures of the partial phases and corona on a single biograph film.

An important paper on the classification of sun-spots was read by the Rev. A. L. Corti, S.J., and illustrated by a fine series of lantern slides selected from the thousands of drawings made at Stonyhurst during the last twenty years. Five types, with a certain number of sub-divisions, were found sufficient to denote the characters of all the spots which had so far been examined.

The chief type, of which the others are probably but phases, is the two-spot formation. The faculæ associated with the different types are also of different characters, and it may be possible to foretell the outburst of a spot by the observation of a certain kind of facula. As an illustration of the use of the type numbers, the life-history of a composite disturbance which crossed the solar disc five times between May 14 and September 4, 1887, was thus described:—

I., II.*b* | IV.*d*, IV.*a* | IV.*a*, IV.*d*, IV.*a* | IV.*a*, I., II.*a* | I.

In the course of the discussion on this paper it became evident that the need for some short system of notation had long been felt by observers of sun-spots, and that, providing the scheme suggested would cover all cases, it would be very valuable. The chairman remarked that possibly a still better system, which would tax the memory less, might be devised on the plan of Herschel's notation for nebulæ.

Prof. Turner exhibited and explained "a cheap form of micrometer for determining star positions on photographic plates." The essential features are a wooden frame to support the photograph, with an attachment carrying a simple microscope containing a scale in the eye-piece. For less than thirty shillings an efficient instrument can be constructed, capable of yielding measures of practical utility. It thus becomes possible for any one to undertake important researches at a much smaller outlay than would be involved in the purchase of a telescope, since there is no lack of material to work upon. Among the investigations mentioned by Prof. Turner as possible with such a machine, were the determination of the positions of nebulæ and comets, and measurements to ascertain the forms of the trails of meteors. Considerable interest in the proposal was displayed, and the hope was expressed that many who now spend their time in fruitless star gazing with small instruments may be induced to undertake these micrometric measurements.

Thursday's meeting was opened with an interesting paper by Dr. Lockyer, in which a comparison was made of the details of the prominences and corona as shown in photographs taken during the recent eclipse at intervals of 2½ hours, by Prof. Langley and Sir Norman Lockyer, in America and Spain respectively. While enormous changes in the prominences were revealed, no change was detected in the structure of the corona in the region of the North Pole, which had been specially investigated. An interesting feature of one of the photographs taken in Spain with an exposure of 40 seconds was the extreme hardness of the moon's limb, notwithstanding the relative motion of the moon during the exposure; the explanation of this unexpected appearance was based on the rapid diminution in intensity of the corona as the outer layers are reached, so that the momentary exposures of the lower corona on the advancing limb of the moon at the beginning of the exposure, and on the following limb at the end, were sufficient to give a strong impression.

The new form of refracting telescope recently erected at Cambridge, chiefly for photographic work, was described by Mr. A. R. Hinks, and illustrated by lantern slides. The object-glass is a Taylor triple lens of 12½ inches aperture, and the chief peculiarity of the mounting is that the portion which is usually the lower half of the tube forms the polar axis, with the eye-end at the top, while the object-glass end is hinged to the other piece, and a plane mirror is placed at the junction. In another paper Mr. Hinks referred to the preparations which are being made for determining the solar parallax by observations of Eros during the coming winter, and exhibited a series of diagrams showing the path of the Cambridge Observatory as seen from that planet at various times. With the aid of such diagrams the observer can see at a glance the most favourable times for making micrometric measurements or taking photographs for the purpose in hand. The importance of the observations of Eros was emphasised by Prof. Turner, who remarked that at the present time the probable error of the adopted value of the solar parallax was equivalent to the thickness of a wicket in the length of a cricket pitch. Unlike the transit of Venus, the observations of Eros would be easily reduced, and the results of the observations would soon be accessible.

A paper on "some points in connection with the photography of a moving object," by Mr. W. E. Plummer, had an important bearing on the photographic method of ascertaining the position of such a rapidly moving object as the planet Eros. A comparison of measurements of the positions of a comet made with a micrometer and those determined from photographs indicated that considerable errors might be introduced in the photographic results on account of the difficulty of determining the epoch of observation. Since the first few moments of exposure on the moving object leave no impression, the middle of the trail does not correspond to the middle of the exposure. In exposures of ten minutes on Eros the danger of error was very considerable. Mr. Hinks remarked that it was hoped to obtain sufficiently strong impressions of the field containing Eros with exposures of one or two minutes, under favourable circumstances, and, moreover, special precautions to eliminate this difficulty had been arranged at the Paris Conference.

Mr. John Herschel described in detail his method of observing and recording the paths of meteors. Special maps are constructed in which the brighter stars are represented by perforations made with needles of various sizes, the side of the paper away from the observer being blue, while that towards him is white. The map being laid on a sloping desk of ground glass illuminated by a night light, the paths of the meteors are ruled in by means of a transparent celluloid ruler having a black edge, The duration of flight is estimated by repeating the letters of the alphabet, minus w, at the rate of five per second, after experience gained from previous practice.

Among other papers presented to the astronomical department was one by Mr. C. T. Whitwell, on "The Duration of Totality of the Solar Eclipse of May 28, 1900." A table which was given illustrated very forcibly the discrepancies between the calculated and observed durations at various observing stations. It was pointed out that to reconcile the observations and calculations by supposing that there were errors in the adopted value of the moon's diameter, or in the position of the observing station, involved the assumption of greater errors than were probable, though each may account in part for the discordance. Another suggestion, due to Mr. Crommelin, was put forward—namely, that, on account of the irregularities of the moon's limb, the beginning of totality is retarded by an amount corresponding to the movement of the moon required to bring the lowest depressions to the edge of the sun's disc after the assumed geometrical boundary has made contact, while for a similar reason the end of totality would be hastened.

A. FOWLER.

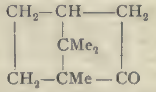
## *CHEMISTRY AT THE BRITISH ASSOCIATION.*

ALTHOUGH the president of section B, Prof. W. H. Perkin, junr., is mainly known as a specialist on polymethylene compounds, his address upon the teaching of inorganic chemistry proved to be of very general interest and was enthusiastically received by a large audience. His contention that the present system of examinations would be advantageously superseded by an inspection of the students' laboratory notebooks was favourably commented upon by Sir H. E. Roscoe and Dr. H. E. Armstrong, although it was admitted that the practical difficulties in the way of such a method are very considerable. The presidential address was followed by the report of the committee on the teaching of science in elementary schools, of which Dr. J. H. Gladstone is chairman; the report consisted principally of a discussion of the returns of the Education Department in so far as they concern the teaching of elementary science. The debate which ensued materially assisted the strong case which was subsequently made out in favour of establishing a separate section of the Association for dealing with educational matters. A paper was next read by Dr. Letts and Mr. R. F. Blake on some problems connected with atmospheric carbonic anhydride and on a new and accurate method for determining its amount, suitable for scientific expeditions; attention was drawn to the variations in the amount of atmospheric carbonic anhydride, and possible explanations of the variations were considered. The authors determine carbonic anhydride in air by absorbing it from about six litres with caustic potash solution, subsequently liberating it by boiling the potash solution with acid in a vacuum and measuring the volume of the carbonic anhydride in a suitable eudiometer. Mr. W. Ackroyd contributed papers on the distribution of chlorine in West Yorkshire and on a limiting standard of acidity for moorland waters. Water from the upper reaches of the West Yorkshire rivers contain from 0·7 to 1·3 parts of chlorine per 100,000, but as the sea or a more populous district is approached, the chlorine number becomes much greater. No cases of plumbism have yet been traced to the solvent action upon lead pipes of water of which the acidity is less than the equivalent of 0·5 part of sulphuric acid per 100,000; this acidity value is therefore tentatively proposed as a limiting standard for potable waters of moorland origin. Dr. T. W. Hime read a paper on the effects of copper on the human body, in which he sought to show that the agitation against the use of articles of food containing small quantities of copper salts is unjustifiable, because a large number of well-known food stuffs contain copper as a normal constituent and because such articles of food exert no poisonous action at all. Reports were received from the committees on the bibliography of spectroscopy and on the preparation of a new series of wave-length tables of the spectra of the elements. Prof. H. B. Dixon and Mr. F. W. Rixon, in a paper on the specific heat of gases at temperatures up to 400°, showed an apparatus for making such determinations at constant volume in which a steel cylinder containing the gas is heated and dropped into a calorimeter; the preliminary results obtained with carbonic anhydride were stated. Mr. F. H. Neville communicated a report on the chemical compounds contained in alloys of which the following is a brief abstract. Intermetallic compounds may be compared with the unstable compounds of the halogens with each other and with sulphur; they often bear a great superficial resemblance to their constituent elements and appear to show marked dissociation, or to form systems in true equilibrium with the liquid mixture of their components.

The intermetallic compounds may be isolated from an alloy (1) by filtration, (2) by volatilisation of excess of a volatile metal, or (3) by removing the excess of metal by means of a suitable solvent. Method (1) has been used by Heycock and Neville, who, on filtering a partially solidified solution of gold and cadmium in tin, obtained a crystalline residue having the composition AuCd; method (2) was applied to the preparation of the same compound by distilling the excess of cadmium from an alloy of gold and cadmium. Lebeau prepared the compounds $SbNa_3$, $BiNa_3$ and $SnNa_4$ by distilling the excess of sodium from alloys in ammonia and nitrogen gas. Debray isolated the compounds $PtSn_4$, $RhSn_3$ and $RuSn_3$, and Le Chatelier obtained $Cu_3Sn$ by the action of dilute hydrochloric acid on alloys containing excess of tin; by methods of a similar nature Heycock prepared $PtAl_3$ and Stead isolated the crystalline substances $Au_4Pb$, $Au_5Pb_2$, SnSb and $Sn_3As_2$. There is, in the application of this method, considerable risk of the solvent attacking the crystals, and Stead has found that the formation of crystals having a core differing in composition from the outside constitutes a serious drawback to the method of partial solution regarded as an independent method of investigation. In the systematic study of intermetallic compounds may be placed first that of the chemical equilibrium of the binary system; this is generally expressed by the freezing-point curve, and has been mainly investigated by Roozeboom and Le Chatelier. Next, and perhaps of equal importance, is placed the microscopic examination of the solid alloys; whilst thirdly, and more limited in applicability, comes the determination of the difference of electrical potential existing between a metal and its alloys. On determining the freezing-points of a series of mixtures of two metals and plotting the freezing-points as ordinates against the compositions as abscissæ, a freezing-point curve is obtained which in its simplest form consists of two branches meeting at an angle—the eutectic angle—lying at a minimum point on the curve. In other cases the freezing-point curve shows a maximum point, but this is not cusped and lies on a gradual change of curvature; the freezing-point curve may thus consist of a series of branches connected by summits and eutectic depressions. It is pretty generally recognised that the eutectic alloy is merely a conglomerate and not a compound, but it is a remarkable fact that the position of the eutectic point on the curve often corresponds closely with some simple molecular composition; cases of this have been observed, not only with alloys, but also amongst organic compounds, by Paternò and Ampolla. The branches of the curve upon which summits lie are caused by the separation of compounds of definite chemical composition from the solidifying magma; the maximum points lie at positions corresponding to the composition of the compound, but Le Chatelier considers that the summit does not necessarily lie exactly at the point indicated by the molecular composition, owing to dissociation occurring in the liquid state. This point, however, needs further investigation. The points upon the freezing-point curve merely denote the temperatures at which solid begins to separate from the magma, but Roozeboom has shown that valuable results may be obtained by plotting, not only the temperatures at which solid begins to separate, but also the temperatures at which complete solidification occurs; in general, the one curve lies below the other, but they intersect or become one whenever the alloy solidifies as a whole. The microscopic examination of the pattern shown by the polished surface of an alloy which has, if necessary, been etched or heated to produce oxidation colours has been worked at principally by Osmond, Charpy and Stead. The existence of coated crystals is made evident by this method, as in the case of the bronzes rich in tin, in which Stead has shown that the $Cu_3Sn$ crystals are coated with CuSn. Le Chatelier has pointed out that in these cases the solid alloy is not in equilibrium, and that annealing will, in general, cause considerable change. Charpy and Stead also consider that evidence of the existence of series of mixed crystals is obtained by microscopic examination. Röntgen ray photographs of thin sections of alloys which contain one transparent metal and one more opaque often give good views of the crystals in the alloy; they were introduced by Heycock and Neville. Laurie and Herschkowitz have studied the potential difference set up between an alloy and the more electro-positive metal contained in it, using a salt of the electro-positive metal as the electrolyte. It is shown that if the alloy consists of a conglomerate of the two metals, the potential of the alloy is that of the more electro-positive constituent; if, however, the two metals are mutually soluble in the solid state, the potential of the alloys will change very gradually with change of composition. Lastly, the existence of intermetallic compounds is indicated by a sudden and large change in potential when the composition of the alloy attains that of the compound. The author notes that although the molecular depressions of the freezing-point of one metal by solution in it of a second point in general to the molecular and atomic weights of the second metal being identical, the evidence is not complete because the second metal may exist combined with the first in the solution. The reading of this report was followed by a lively discussion, in which Sir W. Roberts-Austen, Mr. J. E. Stead, Mr. W. J. Pope, Mr. Stansfield and Dr. H. E. Armstrong took part. Mr. J. E. Stead then read a paper on the mutual relations of iron, phosphorus and carbon when together in cast iron and steel, which was illustrated by a very excellent series of drawings and photomicrographs. Prof. J. A. Ewing and Mr. W. Rosenhain gave a paper on the crystalline structure of metals, in which it was shown that the crystalline character of metals like lead, zinc, tin and cadmium is altered by subjecting them to a severe plastic strain at moderate temperatures; evidence was also adduced in favour of the solution theory of annealing. Prof. Barrett read a paper on the electric conductivity of the alloys of iron, and Mr. C. S. Bradley spoke on some new chemical compounds discovered by the use of the electric furnace. The sixth report of the Committee on electrolytic methods of quantitative analysis was presented; it consisted of papers on the determination of bismuth by Prof. J. E. Reynolds, and on the electro-deposition of iron, by Dr. C. A. Kohn and others. A paper on a simple method for comparing the "affinities" of certain acids was contributed by Messrs. H. J. H. Fenton and H. O. Jones. Oxalacetic acid is decomposed by dilute sulphuric acid into phenylpyrazolonecarboxylic acid in accordance with the equation:—

$$C_{10}H_{10}N_2O_4 = C_{10}H_8N_2O_3 + H_2O,$$

whilst water converts it into the hydrazone of pyruvic acid with evolution of carbonic anhydride. Using decinormal solutions of various acids, it is found that the amounts of carbonic anhydride evolved are inversely proportional to the concentration of the hydrogen ions and hence afford a measure of the affinity constants of the various acids. Mr. H. J. H. Fenton and Miss M. Gosling gave a paper on derivatives of methylfurfural, and Mr. H. M. Dawson spoke on the influence of pressure on the formation of oceanic salt deposits. A paper on recent developments in stereochemistry was read by Mr. W. J. Pope, in which it was pointed out that until a year ago the only known substances exhibiting optical activity in the amorphous state contained an asymmetric carbon atom. Last year, however, Pope and Peachey described a compound which owes its optical activity to the presence in the molecule of an asymmetric nitrogen atom, that is to say, a nitrogen atom which is directly attached to five different groups of atoms. On treating optically inactive methylallylphenylbenzylammonium iodide with silver dextrocamphorsulphonate in a nearly water-free solvent and evaporating the solution, a crystalline mixture of the dextrocamphorsulphonates of dextro- and lævo-methylallylphenylbenzylammonium is obtained which is easily resolved by fractional crystallisation; on treating the aqueous solutions of these salts with potassium iodide solution, crystalline precipitates of the iodides of the two optically active substituted ammonium iodides are obtained. This result proves that ammonium salts are not mere molecular compounds of ammonia with an acid, but are true atomic compounds, in which five atoms or groups of atoms are directly attached to the nitrogen atom. The use of strong optically active acids has also been applied during the present year to the preparation of compounds owing their optical activity to the presence of an asymmetric tin atom. On treating methylethylpropylstannomethyl iodide with silver dextrocamphorsulphonate and evaporating the solution, dextromethylethylpropylstannomethyl dextrocamphorsulphonate is obtained in the crystalline state. On treating the aqueous solution of this salt with potassium iodide solution, dextromethylethylpropylstannomethyl iodide separates as a yellow oil under certain conditions, although under others the iodide becomes inactive owing to the occurrence of racemisation. Similarly, dextromethylethylthetine platinochloride was prepared from optically inactive methylethylthetine bromide, proving that the asymmetric sulphur atom gives rise to optical activity in the same way that the asymmetric carbon, nitrogen or tin atom does. Further, these results prove that the sulphonium compounds contain quadrivalent sulphur, and are true atomic compounds. Since the four elements which we now recognise as able to give rise to optical activity in appropriate compounds are representatives of three groups of the periodic classification, it may be concluded that all the quadri- and quinque-valent elements of the carbon, oxygen and nitrogen families can act as centres of optical activity. Dr. J. B. Cohen, Dr. Divers, Mr. W. Barlow, Dr. H. E. Armstrong, and Dr. F. S. Kipping took part in the discussion which followed the reading of this paper. Dr. A. Lapworth presented a report on our knowledge of the constitution of camphor, in which he showed that the constitutional formula proposed for camphor by Bredt,



is the only one which is in accordance with the facts, and that the Perkin-Bouveault formula must be considered as erroneous. The President, Dr. H. E. Armstrong, Dr. F. S. Kipping and Mr. W. J. Pope joined in the ensuing discussion. A paper was read in which Prof. J. Bredt quoted further evidence in support of the constitution which he has proposed for camphor. Prof. Ossian Aschan, of Helsingfors, gave a paper in which it was shown that on replacing the ketonic oxygen atom in the camphor molecule by two hydrogen atoms the material becomes optically inactive, as it should do if Bredt's formula is correct. The Committee on isomeric naphthalene derivatives, of which Dr. H. E. Armstrong is secretary, reported that Mr. W. A. Davies has continued the study of the action of bromine on betanaphthol, and has obtained two isomeric tribromonaphthols, melting at 155° and 159° respectively. The report of the Committee on isomorphous derivatives of benzene, drawn up by Dr. H. E. Armstrong, was presented. A number of series of homologues of formanilide of the composition $C_6H_5 \cdot NX \cdot COY$, where X and Y are alkyl groups, have been crystallographically examined and numerous crystallographic relationships established by Mr. L. P. Wilson. Dr. Jee has further investigated the isotrimorphous series of 1:3:4-dihalogenbenzenesulphonic chlorides and bromides, and has proved a relation between the stability of the crystalline modifications of the various compounds and their position in the series. Dr. S. Ruhemann and Mr. H. E. Stapleton gave papers on the synthesis of benzo-γ-pyrone and on the combination of thiophenol and guaiacol with the esters of the acids of the acetylene series. Dr. J. B. Cohen and Mr. H. D. Dakin read a paper on the chlorination of the aromatic hydrocarbons and the constitution of the dichlorotoluenes, in which it is shown that the chief products of the chlorination of toluene are the 1:2:3- and 1:2:4- and possibly a little of the 1:2:5-dichlorotoluene. Mr. C. F. Cross gave a paper showing that Caro's reagent acts on furfural with formation of a hydroxypyromucic acid. Mr. H. T. Brown gave an account of his recent work on the diffusion of gases and liquids. Dr. J. B. Cohen read a paper on smoke prevention, contending that the production of smoke should be regulated by some system of Government inspection. Mr. T. Fairley read a paper on the heating and lighting power of coal gas, and stated that in populous districts from 20 to 50 per cent. of the gas produced is consumed for heating purposes or by gas engines. Dr. A. Liebmann contributed a report on recent improvements in the textile industries, in which he observed that the inflammability of artificial silk, which constituted so serious an objection to the use of the material, has now been entirely prevented; the use of artificial silks is, however, limited by their brittleness and susceptibility to damage by damp. Major-General Waterhouse gave a paper on the sensitiveness of silver to light, whilst Dr. J. H. Gladstone and Mr. G. Gladstone contributed some thoughts on atomic weights and the periodic law. Mr. F. W. Richardson gave a paper on Bradford sewage and its treatment, in which it was noted that the presence of large quantities of wool-grease and nitrogenous impurities make the Bradford sewage peculiarly difficult to deal with; the grease soon chokes up the filters and, if it were absent, the sewage could readily be treated biologically. Mr. W. Leach, in a paper on wool-combers effluents, also referred to the unsatisfactory character of the purification methods at present applied to the sewage. Mr. W. B. Bottomley discussed the utilisation of the sewage sludge, and contended that the sludge should be pressed and dried, when it forms a valuable manure. Dr. Letts and Mr. R. F. Blake gave a simple and accurate method for estimating the dissolved oxygen in fresh water, sea water, sewage effluents, &c.

## *SCIENTIFIC SERIALS.*

*American Journal of Science*, September.—The gas thermometer at high temperatures, by L. Holborn and A. L. Day. This is a further study of the nitrogen thermometer with platinum-iridium bulb, which is superior to the porcelain bulb. The correction for expansion is 10° at 500°, 30° at 1000°, and 40° at 1150°. The authors make an elaborate comparison of the gas thermometer with the thermocouples, and determine anew the melting points of a number of metals. Those of silver and gold are 955° and 1064° respectively —Monazite, by O. A. Derby. A single granule of the mineral, no matter how minute, can be securely identified by moistening it with sulphuric acid on a slip of glass and burning off the sulphuric acid over a spirit lamp, when the residue shows the characteristic crystallisation of cerium in radiating needles or isolated crystals of the shape of cucumber seeds.—The spectra of hydrogen and the spectrum of aqueous vapour, by J. Trowbridge. When a condenser discharge is sent through a rarefied gas confined in a glass vessel, the gas cannot be considered dry, for aqueous vapour is liberated from the glass. The four-line spectrum of hydrogen in the solar atmosphere is an evidence of aqueous vapour, and therefore of oxygen in the sun. Conclusions in regard to the temperature of the stars exhibiting hydrogen spectra are misleading if purely based upon conditions of pressure and temperature, for electric dissociation plays a determining part. X-Ray phenomena produced by a steady battery current strongly suggest an electrical theory of the origin of the sun's corona.—A new effect produced by stationary sound-waves, by B. Davis. When a small cylinder, closed at one end, is placed in the stationary sound-wave of an organ pipe, it will not only arrange itself perpendicularly to the motion of the wave, but will move across the wave in a direction perpendicular to the stream-lines. When four such cylinders are mounted in the shape of an anemometer on a needle point, they rotate while the pipe is sounded.—Some interesting developments of calcite crystals, by S. L. Penfield and W. E. Ford. The crystals described show a great diversity of habit, often on a single hand specimen, due to different methods of twinning, together with peculiarities in the development of certain crystal faces. Some peculiar cases of rhombohedral twinning are described.—Method of measuring surface tension, by J. S. Stevens. The surface tension is measured by floating an iron wire on the surface of the liquid, and suspending a piece of soft iron by it. The iron is pulled into a magnetising coil immersed in the liquid by currents which increase until the surface is broken through.

*Annalen der Physik*, No. 8.—Structure, system and magnetic behaviour of liquid crystals, and their mixture with solid ones, by O. Lehmann. The author has succeeded in proving that all the characteristics of crystallisation which the "liquid crystals" described by him do not possess, cannot logically be made part of the definition of a crystal. The only general characteristics of crystals are that they are not isotropic, and that they possess a molecular directive force which governs their shape, and the manner in which their constituent particles are deposited. The directive force is preserved by means of the surface tension, and crystals may therefore be liquid or solid, but they cannot be gaseous. Liquid crystals may be produced by depositing solid crystals on the cover glass of a microscope and gently heating them above the fusing point.—Generation of electricity in liquid air, by H. Ebert and B. A. Hoffmann. A body suspended above liquid air acquires a strong negative charge. This electrification is due to the friction of minute particles of very cold ice suspended in the air vapour. The authors constructed a kind of electrifying machine by means of a tube containing a piece of wire gauze through which the vapour of liquid air was driven.—Spectrum of radium, by C. Runge. The author has located three of Demarçay's lines with the precision necessary to distinguish them from neighbouring solar lines. The lines located have wave-lengths of 4826·14, 4682·346 and 3814·591 respectively.—Influence of a spark-gap upon the generation of Röntgen rays, by A. Winkelmann. The maximum gaseous pressure at which X-rays can be produced may be raised by introducing a spark-gap into the circuit, the best position for it being next the kathode. Hydrogen yields X-rays at greater pressures than air or carbonic acid.—Fall of potential and dissociation in flame gases, by E. Marx. The author proves that an apparent failure of Ohm's law in flame gases is due to the fact that owing to the scarcity of ions the saturation current is soon attained.—Hall effect in flame gases, by the same author. Owing to the great speed of the ions in flame gases, and the difference in the velocities of the positive and negative ions, a Hall effect is much more appreciable in flames than in electrolytes. The author demonstrates the existence of such a Hall effect in the case of a flat Bunsen flame into which a fine spray of a solution of some alkaline salt is blown.

## *SOCIETIES AND ACADEMIES.*

### PARIS.

**Academy of Sciences**, September 24.—M. Maurice Lévy in the chair.—Nature of the combustible gases found in the air of Paris, by M. Armand Gautier. The author has shown in previous papers that the ratio of carbon to hydrogen found by his method of combustion in dilute mixtures of methane and air is 2·4, instead of the theoretical 3. The much higher value of this ratio found in the air of Paris proves that there must be present gaseous substances richer in carbon than methane, such as benzene vapour or its analogues. The experimental results obtained are in accord with the assumption that in 100 litres of Paris air there are 19·5 c.c. of hydrogen, 12·1 c.c. of methane, 1·7 c.c. of benzene vapour and 0·2 c.c. of carbon monoxide.—Experiment in wireless telegraphy with the human body and metallic screens, by MM. E. Guarini and F. Poncelet. The electric waves were generated by a Wimshurst influence machine and were allowed to act directly upon a coherer. It was found that the human body acted perfectly as a screen.—On crystallised calcium aluminate, M. Ém. Dufau. The crystallised aluminate is obtained by heating a mixture of calcined alumina and lime in an electric furnace. Its formula is $CaAl_2O_4$; it forms transparent needles which do not scratch glass.—On Russian flour, by M. Balland. Proximate analyses of three samples of Russian flour are given.

## *A NEW GEOGRAPHY OF PLANTS.*

*Pflanzen- und Tierverbreitung.* Von Alfred Kirchhoff. Hann, Hochstetter, Pokorny, Allgemeine Erdkunde. Fünfte Auflage, von J. Hann, Ed. Brückner und A. Kirchhoff. iii. Abteil. Mit 157 Abbild. im Texte, u. 3 Karten in Farbendruck. Pp. 327. (Prag u. Wien: F. Tempsky. Leipzig: G. Freytag, 1899.)

TO see a portion of my special domain surveyed by an authority in another branch of science appeals to me in a particularly interesting and instructive light, especially if it comes from a man of judgment and broad views. Such a survey may expose any bias, and is likely to open up new vistas. Dr. Kirchhoff, professor in the University of Halle, is a geographer of repute, and naturally approaches the facts of distribution of plants and animals from a point of view different to that of a botanist or zoologist. It is true his book is intended as an introduction to phytogeography and zoogeography for the student of physical geography, and not as a critical essay on these branches; yet its merits seem to demand that we should rank it higher and judge it accordingly. It is not a mere abstract of one of the few well-known treatises on the distribution of plants and animals, made to serve as a text-book for the beginner, but the product of a mind evincing a considerable power of assimilation of matter, necessarily foreign to it in many of its details, and with an admirable grasp of that which is essential. With these accomplishments are combined the gift of a lucid exposition and of a language which is, apart from certain idiosyncrasies of expression, clear and pleasant.

The author reminds the reader in the preface that in the earlier editions of Hann, Hochstetter and Pokorny's "Allgemeine Erdkunde," the corresponding part was written by Dr. A. Pokorny; that the progress of phyto- and zoo-geography has rendered it necessary to recast the whole; and that it is written more especially for the students of geography, and excursions into the domain of the naturalist had therefore to be avoided. Yet geography on the one side, and botany and zoology on the other, overlap to such an extent within the compass of phyto- and zoo-geography, that the author was naturally obliged to fall back over and over again on the botanist or zoologist, who supplied him, if I may say so, with the woof to his warp. It is here where, as one might expect, the weak points of the book become evident; and it is a pity that the author did not avail himself of the aid of a competent botanist for final revision. I suppose the same applies to the zoological details. Reckless statements, as, for instance, that a single individual of *Sisymbrium sophia* produces 720,000 seeds, or that most of the 854 species of the Egyptian flora are introduced, or that Southern Italy (exclusive of Sicily) possesses 3132 species against 9000 for the whole of British India, &c., can hardly be excused by the desire of putting the case as emphatically as possible. Instances of a decided looseness of expression in describing certain facts would have been discovered at once by a botanical critic, *e.g.* when the author says, on p. 18, that the plants derive their "principal food" from the soil, while he applies the same term, on p. 24, to the carbon dioxide of the atmosphere; when he quotes the orchids and aroids of the equatorial zone as examples of parasites (p. 19), although he describes them quite correctly as epiphytes in another place; and again, when he attributes "genuine grass leaves" to the Australian *Xanthorrhoea* (p. 112). Slips, also, like that on p. 162, where the "Rose of Jericho" is figured as *Asteriscus pygmaeus*, a member of the order of Compositæ, but described in the text as a "little Cruciferous plant (*Anastatica hierochuntica*)," or on p. 198, where the author speaks of the "Kompositengeschlecht der . . . Cæsalpinien," call for the helping hand of the botanist. Willows are not wind-fertilised (p. 51); *Rhododendron ponticum* is by no means killed by $-2^\circ$ C. (p. 86); the peach has not originated in Southern Asia (p. 135); there is no transformation of our ordinary grape-vine into an evergreen plant in the tropics; these are statements which should be repeated no longer in text-books. It would be easy to quote a good many more mistakes of this order, but I do not wish to dwell on them more than is necessary to show where, in a future edition, careful revision must be undertaken.

The book is divided into three parts. The first part occupies 139 pages, and deals with general telluric conditions in relation to the organised world, the second (88 pages) with the phytogeographical divisions (Florareiche), the third (100 pages) with the zoogeographical divisions (Faunareiche). The first part is subdivided into five sections, dealing with (1) the reproductive and migratory capacities of the organisms, (2) the natural conditions of vegetable and animal life, (3) the variability of organisms, (4) the Theory of Descent and its geographical proofs, and (5) the general principles of the distribution of plants and animals. To condense this abundance of matter into 139 pages is a very difficult task, and that it has been done on the whole so satisfactorily says much for the judgment of the author.

In the following two parts, Prof. Kirchhoff has set himself the task of characterising the principal geographical divisions of the organic world, relying, of course, on the researches of the recognised authorities in phyto- and zoo-geography, but viewing them from the more comprehensive standpoint of the geographer, as it appeared to him "desirable for a more vivid comprehension of the nature of the countries of the globe." The separation of the vegetable and the animal kingdom into floras and faunas, their distribution in the present, their harmony with the physical character of their respective areas, and their mutual adaptation within each area, are the result of a process of evolution in which the shaping, selecting, separating and shifting forces have been, for both kingdoms, the same to such an extent that a far-reaching parallelism in their geographical differentiation is to be expected *a priori.* This has been, perhaps, too often lost sight of by specialists.

On the other hand, the modern geographer, from the very fact that he starts with conditions bringing about that parallelism, would be naturally led to a more uniform conception of the differentiation of the organic world into floras and faunas. The result of this has been, in Prof. Kirchhoff's case, the almost complete congruence of the two maps representing the "Florareiche" and the "Faunareiche" respectively. Much might be said with respect to the divisions adopted by the author, but space forbids.

The book is abundantly illustrated, and most of the illustrations are well selected and quite to the point; but exception might perhaps be taken to some of the pictures in which the author attempts to represent as many types as possible in one plate, with the usual consequence that the *ensemble* looks unnatural and untrue. The map showing the distribution of the European species of *Asplenium* (p. 89) is not very illustrative and scarcely in place; whilst Kerner's maps dealing with *Tubocytisus* (pp. 90, 91) require thorough revision, although they are excellent so far as method is concerned.

OTTO STAPF.

## FOUNDATIONS OF AGRICULTURE.

*Agricultural Botany—Theoretical and Practical.* By John Percival, M.A.(Cantab.), F.L.S. Pp. xii + 798. (London: Duckworth and Co., 1900.)

THE professor of botany at the South-Eastern Agricultural College at Wye has done well to depart from the utterly inefficient standard of text-books in this subject hitherto set and followed in this country; and, although we do not think the best possible has yet been produced, the present work is so distinctly an improvement, and so clearly sounds the right note, that we have no hesitation in recommending it as *the* elementary handbook for the agricultural student. What it lacks most conspicuously is a clear enunciation of the principle underlying the teaching of botany to students of agriculture, and it will be just as necessary for the teacher using this book, as it is for him who uses others, to emphasise the point of view (lost sight of in nearly all our text-books) that the plant is a focussing centre in which are concentrated the materials gathered by roots and leaves and the solar energy fixed by the chlorophyll-action, so that plant substance—be it in a cabbage, a potato, a crop of wheat or an oak forest—represents a real gain of energy from the surrounding universe, stored up with an equally real recovery of material which would otherwise have been lost to us because dissipated into the atmosphere in an unavailable form. It is this which makes farming, planting, forestry and other branches of agriculture so fundamentally different from the mining industries, where the coal, iron, &c., brought from their storehouse in mother earth are merely temporary sources of wealth representing expenditure of capital.

As regards features of technical detail, there are several interesting departures from the repetitions of previous text-books, and our chief regret is that these are not more original in conception and treatment. For instance, the section on recognition of trees and shrubs by means of twigs in winter is a very welcome one, but it might have been made far better. Again, the part dealing with our common grasses could have been improved by bolder departures from, and less reliance on, Continental and other authorities in common use, though it should be pointed out that the author has, at any rate, provided new drawings of the "seeds" of most of the grasses. This, however, not always with advantage —*e.g.* the very bad figure (210) of Yorkshire fog. Nor do we regard the summary of characters leading to the recognition of grasses by their leaves as either adequate or worthy of the scope of the book; it might have been made much better with a little attention to points not included in ordinary pamphlets on the subject.

These are faults to be remedied in later editions, and must not be allowed to outweigh the really excellent portions of the book dealing with the various large groups of cultivated farm-plants—*e.g.* Chapter xxv., dealing with the hop, is well done, as are Chapters xxxiv.–xxxviii., dealing with those very difficult subjects, the varieties of our cereals. Indeed, we may commend the whole of this part of the work which treats of the classification and special botany of farm crops, with few reservations, such as those hinted at above, as an admirable summary of what the student should direct his attention to in this department of his studies. The general botany is also fairly well done; and although we do not consider the section on "Internal Morphology" quite happy either as regards selection of subjects or treatment of details, we have little but praise for the part dealing with physiology, which is so markedly in advance of the stuff we are too apt to meet with in existing agricultural text-books in this country, that we prefer to dwell only on its merits. The chapters on weeds and on diseases of farm-plants are also distinctly better than those in any previous English works dealing with agricultural botany, and we heartily congratulate the author on his exhibition of capacity in the *rôle* of a teacher of elementary students of agriculture. At the same time, we would point out that much may be done in future editions to improve this subject, and still more in improving and extending the account of the doings of bacteria in the soil. The agricultural student ought to be made to realise that the soil is a matrix, in which the rocks and salts, water and other lifeless constituents, play little more than the subordinate parts of a skeleton or scaffolding, on and between which the real work of conversions, transferences, destructions and constructions of materials necessary for the life of higher plants are being carried out by lower organisms of many different kinds. A vivid picture of the struggles of root-hairs for salts and oxygen, of the relations between anaërobic and aërobic organisms, of the dangers of attack from parasites here, and of the missing of advantageous connections with symbiotic helpmeets there, and of the mutual interactions of the living and non-living factors in keeping up the "fertility," moisture, heat, &c., of the complex soil, would be a fitting subject for a chapter designed to knit together the enormous number of facts here thrown down before the unwary student, and among which he is sure to stumble and flounder.

The ideal here sketched is not an easy one to attain, and we are aware that facts are coming in every day, and that our knowledge of the factors concerned is still in its infancy. Nevertheless, it is no empty compliment to the author to point out that there are indications in the present book that he would be quite capable of putting the crown to his really excellent attempt at an elementary text-book for agricultural students, by adding a chapter which should drive home to this somewhat apathetic class of learners that botany is no longer to be looked upon by them as a luxury or hobby, or as an interesting adjunct to the study of agriculture, but it must be regarded as *the* fundamental science on which all agricultural operations must be based; and such a chapter should make it perfectly clear that the neglect of the principles and facts it embraces is going to spell ruin in the future, just as the intelligent appreciation of its teachings is going to render the properly trained and equipped planter, forester or farmer, master of the situation his forefathers misunderstood.

## OUR BOOK SHELF.

*Surveying and Exploring in Siam.* By James McCarthy, F.R.G.S., Director-General of the Siamese Government Surveys. Pp. xii + 215. (London: John Murray, 1900.)

ABOUT the year 1880 the Siamese Government became convinced of the necessity of accurate surveys for frontier delimitation, and then it was that Mr. McCarthy commenced the long series of explorations which are recorded in the present work, and which have won for him the gold medal of the Royal Geographical Society. To the student of Indo-China, Mr. McCarthy's book is full of extremely valuable information regarding the aboriginal and mountain races of the highlands of the interior, with whom the nature of the author's work brought him into constant contact. Mr. McCarthy has a sympathetic eye for his fellow travellers, and a kindly word for all but the most obstructive of the native officials. From obstruction by this class, the officers of the Siamese Survey have indeed suffered probably more than any other European officials of the Government; inasmuch as the Survey was practically the pioneer department of the modern régime, and it had to contend against the whole of the forces of conservatism, superstition and suspicion which were at the outset arrayed against all innovation of the kind. Against these, for many years, Mr. McCarthy battled almost single-handed, carrying out meantime slowly and laboriously the triangulation of the frontier districts, and himself training his own assistants. The physical difficulties of the country, which can only be thoroughly appreciated by those who have experienced them, and the inevitable sickness which attacks all who spend the wet season in the jungle, further delayed and hampered the work. The author makes light of the difficulties which had to be overcome, but those who read between the lines will see how formidable they were.

As may be supposed, the book is in no way popular or sensational, and the author's dry, matter-of-fact style does not lend itself to picturesque narrative. Yet politics on the north-eastern frontier of Siam during the incursions of the Haw bandits, in the 'eighties, were exciting enough. If one desired to be critical, one might say that the book is composed of short sentences and scrappy and incomplete descriptions. Yet these faults will be condoned by all who take an interest in scientific geography for the sake of the admirable scientific results of Mr. McCarthy's work. And those who seek to know more of the magnificent plateau of Teng, the highest peaks of Indo-China, or the very interesting hill tribes, such as the Ka, Lamet, Meo and Yao, and the Southern Shân races generally, will find more accurate information in the present work than in any other we are acquainted with.

An excellent index, triangulation charts, and a map of Siam in two sheets, with a number of illustrations, complete a work which forms an important addition to the bibliography of Eastern Asia.

*Church Stretton.* Vol. i. *Geology*, by E. S. Cobbold; *Macro-Lepidoptera*, by F. B. Newnham; *Molluscs*, by Robert A. Buddicom. Edited by C. W. Campbell-Hyslop. Pp. 196. (Shrewsbury: L. Wilding.)

THIS is an excellent piece of work, and reflects much credit upon those who originated the idea of preparing an account of the scientific features of the Church Stretton district, and also upon the contributors, editor and publisher of the present volume. Church Stretton is a market-town about twelve miles south by west of Shrewsbury, Shropshire, and has a population of about 2000. The district is interesting from a geological point of view, and Mr. Cobbold's notes (which occupy the greater part of the book) will be valuable to geologists visiting it for the first time, and will also give residents a new interest in their rambles. Most of the fossiliferous localities and the main rock exposures are mentioned or described, so that any one interested in the geological and topographical characteristics can readily find them.

Mr. Newnham gives a descriptive catalogue of the macro-lepidoptera found in the neighbourhood of Church Stretton. The district is a fair field and good hunting-ground for the entomologist, many insects being found in it which do not occur in the lower-lying parts of Shropshire. Future collectors will find the catalogue exceptionally valuable, and will doubtless be able to supplement it.

A list of the land and fresh-water molluscs, with notes on the habits of each species and its comparative local scarcity and abundance, is given by Mr. R. A. Buddicom. The total number of species of British land and fresh-water molluscs is reckoned at 138 (not counting slugs) of which 42 have been found in or near Stretton. A plate containing illustrations of 37 species, natural size, photographed from actual specimens, accompanies Mr. Buddicom's paper.

Other monographs, on the botany, archæology, climatology and ornithology of the district, are in preparation, and if they are of the character of this one they will afford pleasure to every resident or visitor in Church Stretton who has an interest in the study of outdoor nature. The district is fortunate in possessing such a useful guide to its natural characteristics.

*Surveying with the Tacheometer.* By N. Kennedy. Pp. vi + 104. (London: Crosby Lockwood and Son, 1900.)

THIS handy little volume is put forward in the hope of bringing the tacheometer into more general use among land surveyors, its present position in the background being due chiefly, the author thinks, to the fact of the Continental instruments having hitherto been provided with circles divided with 100° to a right angle, instead of 90°, thus necessitating special reduction tables. The publication of a universal method of reduction, no matter what the division value, by Mr. G. Gilman removes the greater part of these objections.

The tacheometer is first minutely described, excellent illustrations being provided for reference, the only essential difference from a good transit theodolite being the insertion of a subsidiary lens between the objective and eye-piece, which, by special adjustment, enables the angular distance between two wires in the eye-piece to be made equal to any desired quantity, decided by calibration on a previously measured base. Subsequent sections deal with the variations introduced by working on inclined ground, details of actual field and office work, concluding with some suggestions on possible methods of utilising existing transit theodolites for tacheometric work. Examples of entries in field-book, plans of surveys, &c., are given at the end of the book. The work is very clearly written, and should remove all difficulties in the way of any surveyor desirous of making use of this useful and rapid instrument.

## LETTERS TO THE EDITOR.

### Ascent of Sap.

PROF. VINES, in his interesting address to the Botanical Section of the British Association, has referred to the problem of the ascent of sap.

We believe Prof. Vines is under a mistake when he states: "Now as to the force by which the transpiration-current is raised from the roots to the topmost leaf of a lofty tree. From the point of view that the water travels in the substance of the walls the necessary force need not be great, and would be amply provided by the transpiration of the leaves, inasmuch as the weight of the water raised would be supported by the force of imbibition of the walls. From the point of view that the water travels in the lumina, the force required to raise and support such long columns of water must be considerable." If we gather the sense aright, this statement involves perpetual motion, as may be seen by imagining both cell-walls and lumina filled with water. According to Prof. Vines, water may be obtained from the cell-walls in the higher parts of the plant with the exertion of a less force than from the lumina. If now we establish a connection, the lumina will draw from the cell-walls, and with a second connection below, an endless circulation will arise. The error arises from supposing that water can be withdrawn from the cell-walls and maintained in upward motion without opposition from the entire gravitational pull. Or, stating the matter in another way, the force which is assumed to uphold the water will also act to resist its withdrawal from the walls. Indeed the withdrawal of water from the cell-walls must be necessarily attended by much higher frictional resistance than would obtain if the supply were received from the lumina. The same objection may, in our opinion, be urged against any exposition of the "imbibition" theory. The underlying fallacy is, in fact, essentially the same as that on which the theory of capillarity and gas-pressure is founded, and which Prof. Vines rejects as "quite inadequate."

Prof. Vines, in further discussing the question, speaks of a tensile force of 360 lbs. to the square inch as being required to bring the sap to the summit of a tree 120 feet high, and states that, not only is there no evidence for the existence of such a force, but that it is even negatived by the indications of the experiments of Hales and Boehm. Without discussing the validity of the supposition that such a force is anywhere required (beyond stating, as our opinion, that the grounds upon which this estimate has been obtained are very doubtful), we would certainly like to know to which of the experiments of Hales and Boehm Prof. Vines refers. So far as we are aware, the indications of Hales' and Boehm's experiments were of necessity limited by the difficulty of putting the water (external to the branches experimented upon) into a condition capable of bearing tension. These investigators, however, did not clearly understand this point. The experiments made by us in the same direction certainly all failed from this cause. The most, then, that can be admitted is that direct observation has never revealed the full state of tension of the sap of a transpiring tree, although, as in the case of some of Boehm's experiments, indications of the existence of tension were conclusively obtained. This is a very different thing from assuming that negative indications have been experimentally obtained. It is hard to see why Prof. Vines should consider the existence of a transpiration force of 20 atmospheres as improbable. It has, indeed, been shown by experiment that the turgescence of the cells of the leaves of many trees is capable of exerting a tractional force of over 20 atmospheres on the water in the conduits.

Prof. Vines dismisses the tension theory as offering no solution to the problem. But how does the matter stand? The more important points may be stated in a very few words.

In the theory of the tensile sap we find full reason for the subdivided structure of the water-conduits and for the structure of their lignified cell-walls (especially as seen in the ingenious mechanism of the bordered pit); stability is conferred on a liquid in tension and liable to the evolution of gas-bubbles by the first, and a minimum of resistance with safety against rupture is secured to the wall by the second. To raise the water through this system the turgescence of the leaf-cells is fully adequate, even were the tension greater than what Prof. Vines demands. Again, in the light of this theory, the advantage of the periodic recurrence of root pressure becomes apparent, as a safeguard against the multiplication of functionless lumina destroying the continuity of the system. On the other hand, those who have discussed this theory have as yet brought to light no fact in vegetable physiology or anatomy opposed to its validity; while many points, *e.g.* the collapse of protoxylem elements, and the occurrence of year-rings, have received in it an explanation.

From the physical point of view, the theory is not only adequate to meet all the requirements of the plant, but the existence of tension in a system of minute chambers having walls at once permeable to water and impermeable to free gas, whether altogether or partially filled with dust-free water, is inevitable. The *onus* of proof does not here lie with the upholders of the tension theory merely because it has come late upon the scene, but its opponents must show how the tensile state is evaded before they can dismiss the existence of the tensile stress in the sap at such times as root-pressure is not the uplifting force.

If, then, the sap is in tension from the nature of the conditions and the leaves active in withdrawing water from above, why deny the adequacy of the explanation?

With regard to the date of publication of our theory, Prof. Vines is slightly in error. Our paper was communicated to the Royal Society in Nov. 1894, and an abstract of it appeared in NATURE in the same month.

### Homochronous Heredity and the Acquisition of Language.

THE question raised by Mr. Stuart-Menteath in NATURE of September 27 (page 524) is one of such general interest to all students of heredity that it is to be hoped that some authoritative expression of opinion will be forthcoming. Even in its present form the query involves the subject of the heredity of acquired characters, and it would be of the greatest importance to have experimental systematic observations carried out if such observations have not already been recorded. So far as my very limited acquaintance with the subject extends, I know of no such experiments. It would be desirable perhaps to widen the scope of the question, and to put it in this form: Take children of different nationalities, say German, French and English; allow them from infancy to hear all three languages indiscriminately. Is there any reason for believing that each child would show a predilection or greater facility for acquiring the language of its country?

R. MELDOLA.

### Autotomic Curves.

BRITISH mathematicians have usually employed the phrase "non-singular curve" to designate a curve which has no double points. This phrase is an exceedingly infelicitous and misleading one, since a *point of inflexion* is just as much a singularity as a *double point*.

The word *autotomic* (self-cutting) has occurred to me as a suitable one to designate a curve which has double points; but the objection to this word is that the phrase "an anautotomic curve" is somewhat offensive to the ear. In the case of media which are not isotropic, mathematicians have evaded a similar difficulty, which would be caused by the use of the word *anisotropic*, by employing the term *aeolotropic*.

Perhaps some of your readers, who have kept up their classics, may be able to suggest a suitable word to convey the idea of a "not-self-intersecting-curve."

A. B. BASSET.
Fledborough Hall, Holyport, October 5.

## THE OPENING OF THE MEDICAL SCHOOLS.

THE subject-matter of the studies comprising the medical curriculum lends itself exceptionally well to the delivering of inaugural addresses. Every October produces its crop of young men and women beginning the study of medicine, and to these are addressed with never-failing regularity an almost constant number of introductory lectures. To those who watch from a distance the perhaps somewhat monotonous rhythm of medical academics, it would appear at least probable that these opening addresses, actuated, as they certainly are, by a perpetually similar motive, would be in imminent danger of suffering from a monotony almost approaching boredom. Medicine, however, and its allied sciences are never at rest, and the constant change in them from year to year forms an almost inexhaustible subject-matter at once interesting to the initiated, and stimulating to the novice. The latter learns, as a rule even in his first lecture, that in embracing medicine as his profession he has not to tread a rigid scholastic entity, but to pick a somewhat circuitous way over a plastic science, which is capable and willing to receive the intellectual footprints of all who are strong enough to impress them.

The third Huxley lecture was delivered this year by Lord Lister, and the authorities of Charing Cross Hospital are to congratulated upon having heard one of the most interesting discourses which it will probably ever be their lot to listen to. Although none of us can for any length of time forget the scientific work for which Lord Lister is celebrated, perhaps few of us are cognisant of his early researches, which, indeed, although perhaps to the superficial observer remote from his later work, according to him—and what better authority can we want—led up to it. All those who have the opportunity of reading this address *in extenso* should do so; it forms another of the many instances of how work of a more or less erudite character led up to results most emphatically utilitarian. This should be remembered and taken to heart by those in authority who are apt to look askance at work, whatever it may cost in the way of perseverance or intellectual effort, which is not immediately productive of utilitarian result.

At the relatively new School of Tropical Medicine, Sir W. MacGregor delivered an inaugural address, taking for his subject some problems of tropical medicine. An interesting point in his discourse was the importance he attached to the study of dysentery. According to him, epidemic dysentery is a scourge of tremendous magnitude, carrying off in some cases 50 to 75 per cent. of the labourers upon certain plantations in Polynesia. His concluding remarks were directed to malaria, and he emphasised in this connection the importance of investigating certain equine maladies on the West Coast of Africa, apparently of a malarial type.

At University College an inaugural lecture was delivered by Dr. Vivian Poore upon science and practice. The lecturer addressed himself mainly to those students who were actually beginning the study of medicine as distinct from the so-called elementary medical sciences. He warned his hearers against adopting the view that all that could not be submitted to laboratory methods was *ipso facto* not scientific, and in this connection drew attention to certain discoveries made by physicians by mere observation, which were from the highest standpoint scientific. Many facts, although explained by bacteriological research, had been discovered by physicians by methods which were purely clinical. Dr. Poore finally pointed out the advantages that should accrue to the students at University College Hospital from the reconstruction it was undergoing, and also how the reconstitution of the University of London might be expected to affect the medical lectureships in the metropolis.

King's College Hospital began the medical session by an old students' dinner, at which Sir John Cockburn presided. The speeches which ensued, although limited, were mainly directed to two subjects, the share which has been taken by the staff in the surgical work in South Africa, and the manner in which the school had been improved during the past year by the establishment of largely increased laboratory accommodation and new lectureships, special reference being made to the subject of pharmacology.

At the inaugural dinner at Guy's considerable interest was attached to Mr. Fripp's speech, which dealt with the work done by the Imperial Yeomanry Hospital in South Africa. This hospital had broken a deal of new ground, and many in a position to judge of the organisation and management of hospitals had expressed the hope that from the demonstration which it had been enabled to give of the way that modern scientific methods could be introduced into the service of the sick and wounded in the time of war, reorganisation of military hospitals upon the lines of the large civil institutions might be effected.

The medical session at St. Thomas's was opened by Sir William MacCormac. In the course of his remarks Sir William pointed out that the present time was a favourable one for entering the medical profession, as London was about to have a great university in reality, and not one in name only, and also that the supply of medical men was not keeping pace with the increase in the population, as shown by the list of medical students entered on the rolls of the General Medical Council.

At St. Mary's Hospital the introductory lecture was delivered by Mr. Stansfield Collier upon the future of the medical student. At the London School of Medicine for Women Mr. Aldrich Blake addressed the students. The subject-matter of both these lectures consisted mainly of advice to the student with regard to the mental habits he should cultivate in approaching his work. An interesting lecture was delivered at the Royal Veterinary College by Prof. MacFadyean. According to the lecturer, the century approaching its conclusion embraces practically the whole history of the veterinary profession in Great Britain. One hundred years ago the Royal Veterinary College was only in the tenth year of its existence, and since then great changes had come over veterinary opinions and practice. With regard to the progress that had been made concerning the causes of disease, glanders and tuberculosis were taken as types. As recently as twenty years ago the opinion that tuberculosis was an extremely hereditary disease was universal among veterinary surgeons, and it was only within the last decade that the erroneousness of this view had been generally recognised. Discoveries which threw light on the cause and nature of maladies necessarily influenced methods of treatment and prevention, and the past century had witnessed great changes in the means adopted to counteract disease. As an instance of this, the almost complete extent to which bleeding has become obsolete may be given. Firing and blistering, although still extensively used, were employed now with more discrimination than formerly, and it seemed upon insufficient evidence.

The inaugural address in the medical faculty of the University of Birmingham was delivered by Prof. Windle, who chose for his theme the very appropriate one of the needs, aspirations and ideals of the Birmingham Medical School. Those who have carefully followed the stages in the development of the great Midland University will not have failed to observe that the main spirit which actuated it when it was, so to speak, on paper, and will continue to guide and distinguish it when architects' plans have been replaced by well-equipped laboratories, is the spirit of scientific research. It will be a great centre for teaching students how to prosecute research in all branches of technical industry. The generous manner in which land has been given by Lord Calthorpe and funds have been supplied by the wealthy citizens of Birmingham has secured opportunities for this purpose, which, when the whole is complete, will probably be unrivalled. Such opportunities are certain to attract students, and especially medical students. It is to be hoped that what is being done at Birmingham will stimulate the formation and endowment of laboratories at the London schools, which, if they wish to attract the mass of students they have done in the past, will be compelled to offer them advantages at any rate not inferior to those that they can find much nearer home.

The students of the Middlesex Hospital were addressed by Prof. Clifford Allbutt upon abstractions and facts in medicine. His concluding remarks with regard to the value of research laboratories are significant, the lecturer confessing that mere observation of disease and morbid anatomy have taken us almost as far as these means can do. Morbid processes should be tracked in their earliest dynamic initiation in order that they can be arrested in these stages. The clinical laboratory of a county hospital should be the centre of enlightenment to all the private practitioners of the district.

The space at our command has only permitted us to reproduce a relatively small fraction of the many interesting and instructive addresses that were delivered during the course of last week. It is sincerely to be hoped that teachers and students alike have profited by them, and that their united efforts will result in the addition to the profession of a body of workers who will be in the truest sense medical imperialists, and who, while working to the fullest advantage the store of learning they have inherited, will not rest content with it, but extend in all directions the empire of medical knowledge, even up to the threshold of the temple of truth.

F. W. TUNNICLIFFE.

## *A NIGHT WITH THE GREAT PARIS TELESCOPE.*

SINCE the final decision was made some years ago to commemorate the Paris Exhibition of 1900 by the installation of a giant telescope which should surpass in size and power any other then in existence, so many varied and contradictory statements have been quoted in the Press, and even in many scientific journals, that a considerable amount of scepticism has been inherent in the minds of most persons interested in the matter. Much of the inaccuracy is traceable to a rather loose estimate being given of the magnification which it was hoped to employ, it being stated that the moon would be apparently brought so close that any object of 1 square metre area could be distinguished. By the extreme kindness and courtesy of M. François Deloncle, to whose initiative the entire instrument is due, the writer was enabled, not only to thoroughly examine all parts of it during the day, but also to take part in the practical astronomical use to which it is already being put during every clear night. A general view of the siderostat is shown in Fig. 1, and the inclusion of the attendant's figure in the upper balcony will give some idea of its relative size. The masonry foundation is about 5 feet 6 inches high, the extreme height of the curved casting carrying the mechanism at the back being about 34 feet. The circular glass mirror seen between the upright fork in front is 6·5 feet (2 metres) in diameter, and about 11·8 inches (30 centimetres) thick, being silvered on the upper exposed side. When not in use a large glass plate is lowered over the silvered surface by a windlass worked from the gallery. As the glass mirror weighs some 3600 kilogrammes, and the iron cell and forked support about 3100 kilogrammes, the friction on the pivot allowing rotation would have been too great for accurate driving if some provision had not been made for eliminating it. This has been successfully done by immersing the base of the fork casting in a bath of mercury, contained in the circular part of the front half of the main base plate, thereby relieving the pivots of about 9/10ths of the total weight. The rotation of the mirror in a vertical plane is also facilitated by the counterpoise weights shown at the ends of the levers acting on each extremity of the horizontal axis passing through the centre of the mirror.

At the western side of the siderostat, above the handles moving the instrument in right ascension and declination, are two telescopes, which by a system of lenses and mirrors enable the observer to read the divisions on two graduated circles without leaving his position. By his side there is also a standard sidereal clock and a telephone.

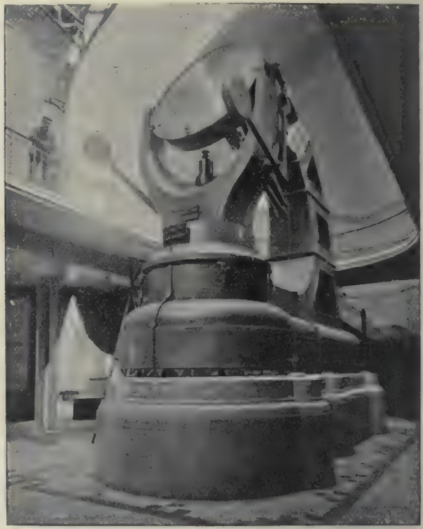

FIG. 1.—The great siderostat, Paris, 1900.

Leaving now the siderostat, and mounting the staircase seen behind it, access is gained to the upper balcony which runs round both sides of the whole length of the building. Fig. 2 is a view taken from the eye-end of the telescope, 200 feet away to the south, and the siderostat can just be seen under the arch at the north end. Above, on the gallery, the circular object-glass is clearly shown in its case. Two of these lenses are to be provided, one specially corrected for visual work, the other for photographic purposes. The lens completed and in position is the latter. The carriages for holding these lenses in

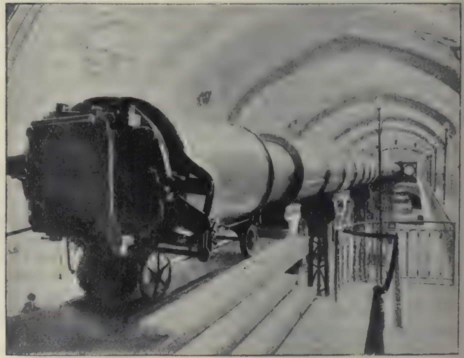

FIG. 2.—Eye-end of the refractor, Paris, 1900.

their massive cells are enclosed in the large rectangular glass case shown in the figure, and being mounted on rails, it is a matter of but a few moments to interchange the position of the lenses with respect to the long tube seen extending from end to end of the gallery. This enormous (and, from an astronomical point of view, probably superfluous) tube is composed of twenty-four sections of sheet steel, each about 8 feet 3 inches (2·50 metres) long, and 59 inches (1·50 metres) in diameter, which are supported on six braced columns rising from the floor below.

At the near end of the tube is shown the massive tail-piece, with the various arrangements for focussing, clamping and rotation of the photographic plate. The focussing is done by traversing the whole of the tail-piece on the two short rails, a motion of about 5 feet (1·50 metres) being allowed, as it is unlikely that the focal lengths of the two lenses will turn out identical.

The lens in position, corrected for the photographic rays, is 49·2 inches (1·25 metres) aperture, and 187 feet (57 metres) focal length. The diameter of the image of the sun or moon at the principal focus will therefore be about 21 inches in diameter.

Rotation of the photographic plate, about 30 inches square, during exposure is necessary on account of the fact that when a siderostat is used, only the central point of the field of view remains stationary, all the surrounding parts having a motion round this as centre. To eliminate this M. Gautier has provided a subsidiary clock, placed to the rear of the eye-end, which, by means of connecting gear to the milled wheel seen on the circumference of the end of the tube, turns the whole tail-piece of the telescope at any desired rate. For visual observations the plate-holder is removed, and an adapter carrying an eye-piece is inserted. The whole of this eye-end section is now covered in by a temporary dark-room.

To admit the light from celestial objects to the mirror of the siderostat, the roof and walls of the building for some 70 or 80 feet are made in two sections, one of which slides to the north, the other to the south, allowing of a clear view from the zenith southwards to within some few degrees of the horizon. This done (requiring some six or eight attendants to work the pulley blocks), all the subsequent movements and adjustments are easily made by two observers. One is stationed at the base of the siderostat, with the handles for working the instrument, telescopes for reading the circles, sidereal clock and telephone all within his reach. Whatever object is selected from the previously prepared working list for the evening, the declination handle is turned until the scale reading seen through the telescope gives the correct declination of the object. Then the hour-angle, or difference between the sidereal time indicated by the clock and the right ascension of the star, is set by means of another handle and the second small telescope. This done, the required object will be near the centre of the field of the large telescope, and the clock being set running to keep it there, the astronomer takes his place at the eye-end to bring it exactly to the centre of the eye-piece. He also has a telephone by his side, and for a space of some two or three minutes there is a continual cross-fire of such terms as "Déclinaison," "Ascension droit," "Doucement," "Au sens contraire," with various endearing terms of admonition in cases of overdoing the movements. Considering, however, the comparatively high power (500) which is the lowest used, it is astonishing how quickly an object is obtained after the setting of the circles. This in itself furnishes an incontestable proof of the extremely accurate adjustment of the siderostat and telescope, both as regards the angle of its polar axis and its position in the meridian. The object being found, all lights are extinguished and a drawing or photograph made as carefully as possible. On the evening it was my privilege to be present, our first object was the Ring Nebula in Lyra (Messier 57). The astronomer in charge was M. Eugène Antoniadi, of the Juvisy Observatory, near Paris, who has started a systematic study of nebulæ with the telescope. This view of the nebula surpassed anything seen before, although frequent observations of it have been made by the writer with a telescope of 36 inches aperture. The great increase of light given by the great glass made it possible to use a highly magnified image, which was at the same time bright enough for the eye to detect detail without any strain.

We next turned to the coloured double star $\beta$ Cygni, after that $\alpha$ Lyræ (Vega), the companion of which was a very conspicuous object. During all this time the instrument was being used in a building containing several hundred people, electric lights all over heating the air, and the huge searchlights and illuminations from the surrounding buildings causing considerable atmospheric glare—conditions under which none but first-class apparatus would be workable. However, owing probably in a great measure to the large proportion of the roof which is opened, the star images were not inconveniently unsteady.

M. Deloncle appears indefatigable in doing his utmost to entertain any one having special interest in his *protégé*. Parties of guests are often there to listen to a short address from him on its construction and installation, after which they go to the eye-piece, and in turn see whatever may be on view. This goes on till after midnight, and then, the last visitor away, all lights are turned out, the lens case opened to permit of air circulation, and about half an hour or more allowed to elapse for the general temperature to be equalised throughout the various parts. We turned next to an object which M. Antoniadi had not previously observed (a small planetary nebula in Sagitta), found it quite easily by the circles and slight subsequent sweeping, and then occupied about an hour and a half in careful drawing. This nebula is G.C. 4572, and M. Antoniadi's drawing appears in the *Bulletin de la Société Astronomique de France*, September 1900.

In sweeping from one object to another, thousands of stars cross the field of view, and it was specially noticeable that no distortion of the star images was to be detected as the mirror was moved to different angles of incidence. With such a high power this is in itself a severe test of the planeness of the silvered surface, and it is worth drawing attention to the fact that the figuring of this mirror by M. Gautier has been done entirely by mechanical means, controlled at every step by the most delicate optical tests.

In connection with the actual work of observing, nothing is so important as accurate clock driving, in order that the astronomer may not be troubled by constantly having to bring the object into the centre of the field. How efficient this instrument is in this respect will be understood when it is stated that during the period for which the clock runs at one winding, about forty-five minutes, the star images do not move sufficiently in the field of a power of 500 to necessitate any adjustment. The angular diameter of the field of view is about 3′ of arc.

By the time M. Antoniadi had finished his drawing of this planetary nebula it was about 3.0 a.m., and approaching daylight. The mirror cover was lowered into its place, the two sliding sections of the roof pulled together over the mirror, and the clock stopped. In a few minutes M. Antoniadi and myself were the only occupants of the gallery, and the institution being already in such regular use that a couple of beds are provided for observers staying all night, we decided that, as it was so terribly hot indoors, we would take up our beds and camp out in the courtyard. We did this, and sleep being somewhat out of the question, spent some time gazing upward in the hope of seeing some forerunners of the August

Perseids, with the usual result of latter-day meteor watching—we saw none. However, it was a novel and exceedingly pleasant experience to be there lying under the stars, the greatest telescope on earth immediately to one's side, the highest building in the world towering over our heads.

It is to be hoped that after the Exhibition is over the telescope will find a resting-place under the Home Government at some station out of the city, where the purity of the atmosphere will allow of its power being efficiently used. C. P. BUTLER.

## TOBACCO.

WHEN Columbus landed in 1492 in the West Indies he found the natives smoking a herb wrapped in a maize leaf, and the name of the herb was Tobago. In 1560 Jean Nicot distributed plants raised from seed to various parts of Europe. These two events give us the clue to the popular and scientific names of a drug the cultivation and preparation of which have now attained such enormous importance that Governments are supported by the revenue derived from its taxation, and colossal fortunes are made by its sale. Some idea of the scale on which the industry is carried on may be gathered from the statistics recently published in the "Year-book of the United States Department of Agriculture for 1899," where we read that during that year 266,661,752 pounds of tobacco, 4,542,016,570 cigars and 4,590,388,430 cigarettes were prepared in the United States alone, yielding a revenue to the Government of 52,043,859·05 dollars.

Small wonder then that the cultivators of so valuable a plant have shown great interest in all the processes of raising, planting, manuring and gathering the crop, and of drying, curing and preparing it for market; or that consternation has arisen in their midst at the origin and spread of a disease which attacks the golden leaf, and bids fair to ruin the crop in some districts. It happens, moreover, that biological problems of wide significance are arising in connection with the complex art of fermenting the leaf so as to obtain the best flavour and strength, as well as in regard to the "Mosaic disease" above referred to, and the experience of Dutch growers, of which an excellent account is now to hand in Koning's "Der Tabak, Studien ueber seine Kultur und Biologie" (Amsterdam and Leipzig: W. Engelmann, 1900), shows that the employment of scientifically trained botanists in the technical laboratories of tobacco plantations is likely to be as usual an event in the future as in breweries and bacteriological laboratories.

The tobacco plant is exceedingly small in the seedling stage—eighteen thimblefuls of seed suffice for a hectare, *i.e.* two and a half acres of land—and is very carefully raised in pots and manured with pigeon's dung, planted out and weeded with extraordinary precautions against numerous enemies, and the leaves eventually picked by hand, sorted, tied into bundles and hung to dry. It is a very exhausting crop, and requires much potash; and an astonishing amount of information has accumulated concerning the effects of different soils, manures, climate and other factors of the environment on the properties of the leaves. Moreover, there are numerous cultivated races in existence in the various tobacco-growing countries, as always occurs with planted crops.

During the process of slow drying the leaf may remain alive for two to three weeks, and the contained starch is converted into sugar, and further alterations result in an increase of acids. Proteids diminish and amines increase, but the nitrates and alkaloids (nicotin) should undergo no change. The slow alterations referred to are essential, and due to enzyme and other actions in the still living leaf; in artificially or rapidly dried leaves the arrest of such changes materially affect the flavour and burning of the tobacco, and naturally much turns on the age and quality of the leaf itself, the soil and season and other conditions of growth, &c.

The dried or "cured" leaves are next submitted to fermentation, a process of vital importance in the opinion of the tobacco expert, since it is this which determines the finer flavours and odours of the manufactured product. Fermentation is started by damping heaps of 15,000 to 30,000 lbs. of the dried leaves, packed in a special manner, and carefully watched by experienced workmen as the temperature rises. The process occupies three to four months, and the leaves are turned about once a month. The temperature rises to about 50–56° C., and a loss of vapour, accompanied by a sweet and sharp odour, is noticed. The reaction may be neutral, though in some cases ammonia is given off, due to the action of undesired bacteria.

As would be expected, the fermentation is always accompanied by bacteria; but it has long been in dispute whether the essentials of the process are due to bacteria or to the action of special enzymes in the cells of the leaves.

Suchsland's researches had convinced him, not only that the fermentation is due to bacteria, but that a peculiar species of bacteria was specially concerned in the production of the approved flavour, and that the desirable properties of Cuban tobaccos could be imparted to inferior growths by introducing this species into the fermentation. Loew, on the other hand, maintained that the aroma and flavour depend simply on the action of enzymes or other cell-contents in the leaf itself.

Koning has investigated the various bacteria found in the fermenting heaps, and followed the changes induced in the tobacco.

Put generally, the fermented tobacco undergoes little or no change as regards the total nitrogen or the nicotin, but organic acids diminish, and the sugars and nitrates are destroyed, and various aromatic substances are formed which affect the quality of the product.

Among the bacteria isolated Koning claims to have found the species concerned in this remarkable neutral fermentation, and which imparts the aroma and flavour desired, and thus confirms Suchsland's results. He states that tobacco infected with the specific bacteria, fermented and made up, and then handed to experts, was selected by the latter as the superior from specimens containing other kinds. There is more than a touch of the dramatic in this scene of the experts sitting down to smoke a pair of cigars each, in packets of two, and labelled *a* and *b*, *c* and *d*, &c., only; but the evidence appears conclusive.

During the last ten years increased attention has been drawn to a disease of tobacco leaves, which causes irregularly alternating light and dark patches, and is known as the "Mosaic disease." Koning has established that this is infectious, and is carried through the fields by the fingers of the workmen who "top" the growing plants by pinching off the buds. He has examined the various fungi known to cause leaf-diseases in tobacco, and cannot refer it to these, and the presumption that it is a bacterial disease was strengthened by finding that certain manured soils were almost sure to have badly diseased plants on them; and that experiments showed that if a bit of diseased leaf, or a little of the sap from such is rubbed into a wound, the young leaves formed above the wound contract the disease. The same result follows if such sap is placed at the roots of healthy plants. But infection fails in all these cases if the sap is previously boiled.

Here may be mentioned that Adolf Mayer had proved the infectious nature of the filtered sap in 1885, and Beijerinck, working at this disease a short time ago (1898), had come to the conclusion that since no organisms could be isolated from the sap—the infectious nature of which he also proved—which will reproduce the disease, and since the same sap *filtered through porcelain* still infects the plants, unless it was previously sterilised by heating, the causal agent must be a *contagium vivum fluidum*—a something of the nature of a poisonous enzyme, which not only diffuses through the plant-membranes—*e.g.* the cell-walls of root-hairs—but increases as it passes from cell to cell.

Koning confirms Beijerinck's principal results, but concludes that since the infecting fluid may be heated to 100° C. for a few minutes without losing its powers, whereas alcohol and glycerine destroy the virulence, as also does *repeated* filtration through porcelain, the active agent is *an extremely minute organism*, which can traverse the pores of a filter. He compares the results with those obtained with the virus of various animal diseases from which no organism has as yet been isolated.

It should be borne in mind that the existence of organisms small enough to pass through a porcelain filter has been accepted by several authorities.

When we reflect that well-studied micrococci are only 0·5 – 0·8 $\mu$ in diameter, and that the wave-length of those light rays corresponding to the sodium-line D is about 0·6 $\mu$, some of these matters become less astounding: organisms 1/5th to 1/10th this size would probably be well beyond the powers of our best lenses, and would roll through the pores of a filter as shot through the meshes of a sieve.

It thus appears that—without regarding the work as quite conclusive, which it is not—we have here important contributions to several most weighty biological questions centred about the culture of an economic plant.

## *NOTES.*

The International Congress of Botany was opened in Paris on the 1st inst., and was in session until Tuesday last. M. Prillieux was the president.

The new science laboratories at King's College, London, are to be opened on the 30th inst. by Lord Lister.

Another death from plague has occurred in Glasgow, bringing the number of fatal cases in hospital since the outbreak up to six. A fatal case of plague is also reported from Llandaff.

A Reuter telegram announces the arrival at Copenhagen, on October 4, of Lieut. Amdrup and all the members of his expedition. From July 18 to September 2 the expedition, while engaged on the coast of Greenland, explored and mapped out a stretch of land hitherto entirely unknown and extending from Cape Dalton, 69°28′, to Aggas Island, 67°22′. Lieut. Amdrup is reported to have brought with him important collections, the results of his researches. The *Antarctic* reached Tasiusak on September 11, and sailed thence on her return journey on September 18.

The *Athenaeum* states that the Kolthoff Arctic Expedition has succeeded in bringing to Sweden a male and a female calf of the musk ox (*Ovibos moschatus*, Gmelin). As soon as the animals appear to be acclimatised they are to be set free in the northern mountain regions, where it is thought they will speedily increase in number, as they are very prolific. Herr Kolthoff has great faith in the future importance of the musk ox, not so much as an article of food as on account of its thick brown wool, which is said to be remarkably strong.

The petrified remains of the extinct rhamphorhynchus have been discovered in the stone quarries of Eichstätt, Bavaria. It is stated that the teeth and fingers are very distinct, and that the membrane between the fingers is visible in places.

According to the *Exchange Gazette* of St. Petersburg, the question of the official introduction of the metric system of weights and measures into Russia has been decided in principle in an affirmative sense. The Ministry of Finance is now considering in what manner, and when, the projected reform shall be carried out.

The trustees of the American Medical Association have established a fund of 500 dollars, to be expended annually for the encouragement of scientific research; but no individual is to receive more than 100 dollars at one time.

The lecture arrangements of the London Institution for the session terminating on February 28 next have now been completed. The science lectures are as follows:—"The Rise of Egyptian Civilisation," by Prof. Flinders Petrie; "The Earth's Beginning," by Sir Robert Ball; "The Earth's Earliest Inhabitants," by Prof. Grenville Cole; "The Caves of Jenolan," by Mr. F. Lambert; "The Tercentenary of the Science of Electricity," by Prof. Silvanus Thompson; "The Evolution of the Brain," by Dr. Alex. Hill; "Modern Aeronautics," by Mr. Eric S. Bruce; "The First Ascent of Mount Kenya," by Mr. H. J. MacKinder; The Effect of Alcohol on the Nervous System," by Prof. Victor Horsley; "The Decorative Art of Primitive Peoples," by Prof. A. C. Haddon; and "Aquatic Autocrats and Fairies," by Mr. F. Enock. The Christmas course, intended for juveniles, is to be delivered by Prof. W. B. Bottomley, and will be devoted to "Structure and Colour," "Insect Visitors," "Unbidden Guests," and "Place in Nature."

The next meeting of the Royal Microscopical Society will be held on Wednesday, the 17th inst., when Part ix. of a report on the recent Foraminifera of the Malay Archipelago will be presented. Preceding the meeting there will be an exhibition of slides and models of skin structure, by Mr. F. W. Watson Baker.

The first monthly general meeting of the new session of the Institution of Mechanical Engineers will take place on Friday, October 19, when a paper, entitled "Observations on an Improved Glass Revealer for Studying Condensation in Steam Engine Cylinders and rendering the Effects Visible," will be read by Mr. Bryan Donkin, and discussed.

A new monthly meteorological journal has recently made its appearance in Holland, and bears the name of *Nederlandsch Tijdschrijt voor Meteorologie*. The style of the journal is popular in character.

The current *Geographical Journal* publishes further details as to the programme of Dr. Sven Hedin's journeys in Northern Tibet and neighbouring regions for the present year. At the time of sending his last letter, on June 27 last, the explorer was about to start for the Chamen Tagh, whither his caravan had already preceded him, his intention being to cross the Astyn Tagh and Koto-Shili ranges, so as to obtain a geological section of the country, and correct his route with that of his former Tibetan journey. After returning to his headquarters in the Chamen Tagh, he hoped to make his way across Northern Tsaidam to Sachu, and thence west to the old bed of Lob Nor, continuing his investigations of the latter end of the ruins in its vicinity. Thence he proposed to carry a chain of altimetric observations to Kara-koshun and Chaklik. He hoped to arrive at the last named point by about January 1, 1901.

A SLIGHT earthquake disturbance in Bombay, on Monday, September 17, is noted in the *Pioneer Mail*, Allahabad. Only one of the instruments at the Colaba Observatory recorded it. The disturbance began at about 3h. 48m. a.m., Bombay time, and reached its maximum at about 3h. 54m. The larger movements ceased at 4h. 2m., and the after-tremors at 4h. 16m. Thus the whole disturbance lasted fully 28 minutes. It was not a distant earthquake, nor was the movement large. The apparent distance of the origin from Bombay may have been about 500 miles. The same journal also records the occurrence, on September 10, of a slight earthquake shock in Madras.

THE New York correspondent of the *Lancet* states that the Chicago Board of Education has established a department called "Child-study and Pedagogic Investigation." The examination is undertaken for the purpose of determining the mental and physical status of the school-children. Examinations were at first limited to the determination in each pupil of the following points: Height, height sitting, weight, ergograph work, strength of grip right and left, hearing right and left, and acuity of vision. In addition to this, obvious developmental defects have been noted. The number of children examined down to the present time is 5636. The conclusions thus far reached are that there is a physical basis of precocity, that dull children are lighter and precocious children heavier than the average child, and that mediocrity of mind is associated with mediocrity of physique. A similar result was obtained in the examination of 33,500 school-children in St. Louis in 1892 by Dr. W. T. Porter. This is the first instance of a municipal board in America appropriating money for research work, and its effect may be far-reaching.

THE German Consul in Payta-Piara (Peru) reports the discovery of large rubber forests on the Niera River, a branch of the Amazon. An expedition has been organised to start for the interior to secure the right to collect the rubber. The increasing demand for rubber has drawn attention to the advantages of cultivating gutta—a leading product of Java and several of the neighbouring islands. A recent number of the *Straits Budget* points out that gutta trees growing wild cannot meet the growing demand which must soon outrun the supply unless gutta plantations extensive enough to meet future needs are laid out. Gutta leaves have been freely resorted to in order to eke out the supply. A company has recently been formed at Batavia to develop this branch of industry.

A LENGTHY account (based on the preliminary report presented to the R. Accademia dei Lincei) of Prof. Grassi's malaria experiment appears in the last number of the *British Medical Journal*, from which we glean the following particulars. In making the experiment, which took place in the plain of Capaccio, near Salerno, two objects were kept in view, viz., (1) To afford an absolute proof of the fact that malaria is transmitted exclusively by the bite of *Anopheles* mosquitoes; (2) to found on the results of recent research a code of rules to be adopted for freeing Italy from malaria in a few years. The experiment consisted in protecting from malaria railway employés and their families living in ten railway cottages and at the stations of S. Nicolò, Varco and Albanella, situated along the Battipaglia-Reggio Railway. They numbered 104 persons, including thirty-three children under ten years of age, Of these 104 individuals, at least eleven, including four children, had never suffered from the disease, not having previously lived in a malarious district; a certain number, it appeared, had not suffered from it for two or three years, and all the others, that is to say, the large majority, had suffered from it during the last malarial season, some of them even in the winter. During the malarial season, the health of the protected individuals was good, with the exception of a few cases of bronchitis and a case of acute gastro-enteritis. None of these cases were treated with quinine. The 104 persons, with three exceptions, had remained free from malaria up to September 16th, the date of the report. From the report it is evident that the twofold object of the experiment has met with every success, and it certainly looks as if it will be possible to free Italy in a short time from malaria, and that the much dreaded plain of Capaccio (excepting for the *Anopheles* infected by malaria germs, from which one can easily protect himself) is one of the healthiest places in Italy.

THE current issue of the *British Medical Journal* gives particulars of the new bacteriological laboratory of the Melbourne University, at present in course of erection. The large hall of the laboratory will afford accommodation for eighty students. Situated on the ground floor there are four research laboratories and one preparation room specially fitted for the professor of pathology, who has, in addition, one room set apart for pathological-histological work and one for chemical pathology. Steam is laid on all over the building for both heating and sterilising purposes. One room has been set apart as a plague laboratory, having germ-proof windows and doors. The walls are covered with tiles made of opaque glass and the floor with lead, so that it can be flooded with antiseptics in case of accidents. In the building there are rooms devoted to microphotography, the preparation of media of all kinds for the sterilising and disinfecting of all utensils, and departments for numerous other purposes. The department is subsidised by the Board of Public Health, by the Ministry of Agriculture, by the Metropolitan Board of Works, by the City Council, and by other municipalities, who contribute between them about 800*l.* per annum. The duties of this bacteriological department consist in the examination of water and milk supply, of investigating diseases which are discovered at the abattoirs and amongst stock, and analysing the effluence from the sewage farm. It is also prepared to assist the Board of Public Health, on behalf of the medical profession, in diagnosing diphtheria, typhoid, tubercle and cases of plague. It is expected that the building will be opened in March next.

A NEW use for kites is brought under notice in the latest issue of the United States *Monthly Weather Review*. An exhibition has recently been given in Chicago showing how those within a besieged town or other inaccessible place can use the kite line to carry a telephone, with its separate telephone wire, through the air, and let it drop from the kite upon a distant place while the kite still remains in the air. By using a very large box kite and attaching to the kite line a little way below the kite a pulley through which runs the telephone wire, the telephone may be dropped from the pulley while the insulated wire keeps up the connection with the man at the kite reel. Of course, at the present time (as is pointed out in the *Review*), when kites have rarely been sent out with more than two miles of wire, which corresponds to a horizontal distance of much less than two miles, this method does not promise to put into communication persons separated by a great distance, but it may be very useful for short distances.

IN order to enable Essex dairy farmers and ladies engaged in dairying to gain an insight into agricultural education and the organisation and practice of the agricultural industries of Denmark, the Essex Technical Instruction Committee arranged a visit to that country in May last, when thirty-one persons spent a week there in visiting the agricultural schools, dairy farms, butter factories, &c. The excursion (judging from the careful report just issued from the County Technical Laboratories, Chelmsford) seems to have been in every way a great success. The members of the party were impressed with the thriving condition of agriculture in Denmark, the happy position of which is attributed in the report to legislation, education and co-operation. Visits such as that under consideration cannot, if properly organised, fail to bring about useful results.

THOSE interested in the phylogeny of the Vertebrata will be pleased to hear of the discovery in the seas of Alaska of a new representative of the Enteropneusta, in the form of a species allied to the typical group of Balanoglossus. This new form, which it is proposed to call *Harrimania maculosa*, is described by Mr. W. E. Ritter in Part 2 of "Papers from the Harriman Alaska Expedition," now in course of publication in the serial last quoted. The new form leads its describer to conclude that the notochord of the Enteropneusta is undoubtedly homologous with that of the Vertebrata. It is specially noticeable in that it consists of two parts; the anterior corresponding with the same structure in the other members of the group, while the additional posterior moiety is connected with the æsophagus. This latter portion is peculiar in that it persists throughout life. Harrimania, which is considered to be the most primitive member of the group, instead of burrowing like Balanoglossus, lives under stones, where it often makes its way through the mud at the plane of contact between the latter and the stone beneath which it is concealed. While some examples were only found at extreme low tide, others occurred much nearer high-water mark than is the case with any other Enteropneusta.

THE last published number of the U.S. *Monthly Weather Review* (June) contains a note by Prof. E. B. Garriott on the extension of the Weather Bureau work, which constitutes one of the most substantial advances in the history of that institution. The West Indian branch was established in 1898, and at the present time practically all the cable islands and ports of the West Indies and the Carribean coast of South America receive advices regarding tropical storms. The West Indian observing stations number thirteen, and hurricane warnings are displayed at more than a hundred points. Telegraphic reports are now also received from well-distributed Mexican stations. It is believed that the reports received from the northern and western parts of Mexico will lead to a better understanding of the important storms which sweep north-eastward from the tropical Pacific and cross the United States to the Atlantic. Reports from the extreme north-west of Canada have been added within the last two years and have furnished valuable data regarding the movements of North Pacific storms. The Weather Bureau has consequently reports from an area extending over more than 42° of latitude and 65° of longitude. The advantage afforded by these widespread telegraphic stations can hardly be over-estimated.

THE *Philosophical Magazine* for October contains an interesting paper by Mr. R. J. A. Barnard, of Melbourne, on the annual march of temperature. The author has examined the observations for forty years at Melbourne and has divided them into two groups, 1859–78 and 1879–98. In each group the average for every day is obtained and smoothed twice by replacing the temperature of each day by the mean of the five consecutive days of which the particular day is the middle. The results of the second smoothing show that in the second week of March the temperature begins to drop rapidly, reaching a secondary minimum for each curve on the 19th. It then rises again to the extent of 2°·5 during the next week, reaching a maximum on the 25th and 26th, the data being the same again for both groups. The spells are not so marked as those found by Dr. Rijkevorsel for Europe, owing probably to the more uniform conditions of the southern hemisphere. The results show that a period of less than forty years is not likely to give any trustworthy information about spells, and that the division of the observations for any particular place into groups of twenty years and the comparison of them in the way specified appear to be satisfactory methods of finding out whether such spells really exist.

THE rise and fall in the level of a lake, produced by the mechanical action of wind, is strikingly shown in a short paper contributed by Prof. A. J. Henry to the U.S. *Monthly Weather Review* for May. Continuous records of lake level at four points, viz. Amherstburg, Ontario, mouth of the Detroit River, and Buffalo Harbour, Lake Erie, were considered in conjunction with continuous records of wind direction and velocity and atmospheric pressure made at the Weather Bureau offices in Detroit and Buffalo; and a relation between the wind and water is clearly shown when the two sets of records are plotted under one another. It has been known for some years that general winds, as distinguished from local winds, blowing parallel to the longer axis of the main body of the lake, have a tendency to heap up the water at the end of the lake toward which they blow, and to depress it at the opposite end. Owing to the convergence of the shore lines at Buffalo, the heaping up of the waters in that harbour, under the influence of a south-westerly wind, becomes a serious menace to the safety of wharf and dock property. Likewise, owing to the shoal water at either end of the lake, a decrease in the available depth in the harbours and channels produces vexatious delays and frequent groundings.

PROF. HENRY's examination of the facts referred to in the foregoing note shows that when high water exists at Amherstburg it is always low water at Buffalo. The synchronism of the times of high water and low water at the two places is almost perfect. The period of oscillation is likewise fairly constant, ranging from six to eight hours for a half oscillation, and from twelve to sixteen hours for a whole oscillation. The computed time of a whole oscillation, assuming the lake to have a mean depth of 50 feet, is, roughly speaking, seventeen hours. While the information on the subject is as yet too fragmentary to admit of drawing trustworthy conclusions, this much seems to be apparent: the oscillations are stationary rather than progressive. A wave of water is not propagated, in the ordinary sense of that word, from one end of the lake to the other, but the whole lake oscillates about a pivotal or nodal line, which, in the case of longitudinal oscillations, may be said to cross the lake about the longitude of Fairport, Ohio. Although there is no instrumental evidence of the fact, it may be assumed that, as in the case of similar oscillations in other land-locked bodies of water, the oscillations at the nodal line are zero, increasing to a maximum at the respective ends of the lake. Prof. Henry concludes by saying that it is within the range of probability that the occurrence of the more pronounced oscillations can be forecast by the Weather Bureau at no distant period.

To the *Entomologists' Monthly Magazine* for October, Mr. R. McLachlan contributes an abbreviated translation of an article, by M. A. Lancaster, on the swarms of a species of dragon-fly (*Libellula quadrimaculata*) which were observed in Belgium on June 5 and 10 last. On both occasions the temperature was very high, and the insects flew against the wind. The translator is of opinion that nothing certain in regard to the causes of these remarkable migrations has hitherto been ascertained. "As a rule," he writes, "the multitudes are so vast as to make it difficult to believe that all can have been bred within a very limited area. On the contrary, it rather looks as if the individuals in a certain initial locality, being seized with an uncontrollable migratory impulse, were progressively joined by others till the accumulations formed the ultimate swarm. A part of the second swarm seems to have reached England.

IN an exhaustive paper read before the Manchester Literary and Philosophical Society (*Memoirs*, vol. xliv. Pt. 4, pp. 1–8), Mr. Thomas Thorp describes his modification of the diffraction process of colour photography, first put forward by Prof. Wood. The difficulty of determining the correct degrees of rulings necessary for giving certain colours by Prof. Wood's arrangement is obviated by adjusting several copies of a grating having the same spacing at angles to each other, the angles giving the best colour combinations being found by experiment. Full details are given of the method of obtaining the celluloid copies from an original metal reflection grating. A diagram is included to illustrate the procedure for obtaining stereoscopic views with the apparatus.

IN the *Astrophysical Journal* (vol. xii. pp. 30–48), Herr J. Hartmann, of the Astrophysical Observatory at Potsdam, gives a useful and interesting series of suggestions on the design and critical adjustments of photographic spectrographs intended for observational work of a high degree of accuracy.

IN *Science* for September 28 is to be found an article on the "International Catalogue of Scientific Literature" from the pen of Sir Michael Foster, in which it is stated that more than forty-five complete sets of the work have already been subscribed for in the United States, and that, therefore, the catalogue will be begun at once.

MANY of our readers will be pleased to know that the recently delivered Huxley lecture of Lord Lister is to be had *in extenso* in both the *Lancet* and the *British Medical Journal* for Saturday last.

THE last part published (vol. xii. Part 4) of the *Journal* of the College of Science, Tokyo, gives evidence of the continued activity of the Japanese University in zoological research, in two valuable papers:—Further observations on the nuclear division of Noctiluca, by C. Ishikawa; and Notes on some exotic species of Ectoparasitic Trematodes, by Prof. S. Goto, both well illustrated. This number also contains the commencement of an enumeration, by T. Ito and Prof. J. Matsumura, of the flowering plants of the Lûchû Islands, the rich and interesting flora of which is at present but imperfectly known.

THE second volume of the elaborate "Cyclopedia of American Horticulture," by Prof. L. H. Bailey, Dr. W. Miller and others, has been published by Messrs. Macmillan and Co., Ltd. The volume extends from E to M, and is to be followed by two others. There will be more than two thousand original illustrations in the complete work, and the text will be on a proportionally large scale. The scope of this remarkable undertaking may be judged from the sub-title, which certifies that the complete work will comprise "suggestions for cultivation of horticultural plants, descriptions of the species of fruits, vegetables, flowers and ornamental plants sold in the United States and Canada, together with geographical and biographical sketches." Our review of the work will be deferred until the appearance of the final volume.

NEW editions of several established works have been recently received. The fifth edition of "Quantitative Chemical Analysis," by Dr. Frank Clowes and Prof. J. B. Coleman, has been issued by Messrs. J. and A. Churchill. The book provides a sound course of work both in manipulation and analysis, and is well in touch with modern methods. Among the additional matter we notice a description of a new and ingenious method of determining melting-points, a special apparatus for the rapid filtration and ignition of precipitates, and an improved form of condenser for use in the distillation of liquids.—The principles and practice of paper manufacture are presented in a form suitable for students in "A Text-book of Paper-Making," by C. F. Cross and E. J. Bevan (E. and F. N. Spon). The second edition of the book has just appeared.—Another second edition is "Agricultural Zoology," by Prof. J. R. Bos, translated by Prof. J. R. Ainsworth Davis. An appendix has been added, containing an instructive statement of conditions which determine the appearance of harmful animals; also the general principles as to the means to be employed against them, and lists of pests classified according to their habitat. A full index has also been added.—Now that attention is being given to nature study in rural schools, Mrs. Brightwen's writings upon animal and plant life should receive additional admirers. Her books are of a kind that cannot be too widely known, so we are glad to see that Mr. Fisher Unwin has just issued new editions of "Wild Nature Won by Kindness" and "Glimpses into Plant Life."

THE "Memoirs and Correspondence of Lyon Playfair" was fully noticed in our issue for December 7 last, so that it is now unnecessary for us to do more than to state that a "popular" edition of the book has just been issued by Messrs. Cassell and Co., Ltd.

THE new issue of the *Journal* of the Royal Agricultural Society of England, contains, as usual, a number of interesting and valuable articles, among which may be mentioned an account, by Dr. Fream, of the York meeting of the society, "The Trials of Steam Diggers at York," and an obituary notice (with a page portrait after Herkomer) of Sir John Bennet Lawes.

*Nature Notes* for October mentions that an avocet was shot near Penzance in the spring.

IN the October number of the *Journal of Conchology*, Mr. A. G. Stubbs concludes his synopsis of the freshwater and land molluscs of the Tenby district.

IN the last annual "General Report of the Geological Survey of India," a voluminous book of 258 pages, the results of much industrious labour by the officers of the Survey are summarised. Considerable activity is being displayed in the prosecution of chemical and palæontological research, and the field-work has been directed towards elucidating economic questions as well as others purely geological. Part iii. of this work contains individual "progress reports" by various officers of the Survey, which consist of papers dealing, not only with economic matters such as auriferous reefs and coal-fields, but also with various questions of considerable geological interest.

UNDER the title of "A List of Works on North American Entomology," the U.S. Department of Agriculture, Division of Entomology, have issued, as No. 24 of the new series of their *Bulletin*, an extremely useful classified index to the most important publications relating to the various orders and families of North-American insects. It has been compiled under the direction of the entomologist, Dr. L. O. Howard, by his assistant, Mr. Nathan Banks. The idea is excellent and might well be adopted for other publications of a similar character respecting the insects of other countries. Such an index cannot be complete, but so many of the most important works on the subject are included that it will be easy for a student taking up the study of any special branch of North American insects to feel his way by this bibliography at the commencement and to enlarge his knowledge on a good foundation as he progresses.

THE latest part of the *Journal* of the Asiatic Society of Bengal (that issued on July 9) is wholly taken up with Sir George King's "Materials for a Flora of the Malayan Peninsula," a portion of which has been written by Dr. O. Stapf, of Kew.

IN addition to the usual "notes" and proceedings of Irish Societies, the October issue of the *Irish Naturalist* contains an interesting communication by Mr. C. B. Moffat, entitled "The Habits of the Hairy-armed Bat."

WE have received a copy of the *Papers* and *Proceedings* of the Royal Society of Tasmania for 1898–1899 (issued June 1900). It contains a useful list of Tasmanian mollusca, by Miss Lodder; several petrological papers, by Mr. W. H. Twelvetrees and Mr. W. F. Petterd, in which limurite, haüyne-trachyte, felsites, nephelinite and other rocks are described; also a note by the same authors on bones of Tasmanian labyrinthodonts. Numerous other natural history subjects are dealt with.

AMONG recent American and Colonial reprints we have to note the following:—Contributions to the U.S. National Herbarium, the plant covering of Ocracoke Island, by Thomas H. Kearney, jun.; and Stigmonose, a disease of carnations and other pinks, by Albert F. Woods; both issued by different divisions of the U.S. Department of Agriculture; Progress of plant breeding in the United States, by Herbert J. Webber and E. A. Bessey, reprinted from the year book of the U.S. Department of Agriculture for 1899; and Observations on the eucalypts of New South Wales, parts 5 and 6, by H. Deane and J. H. Maiden, from the *Proceedings* of the Linnean Society of New South Wales.

A SMALL pamphlet, issued by the Joint Agricultural Council of the East and West Ridings and of the Yorkshire College, containing a list of one hundred Yorkshire weeds, should be useful to farmers. It will be supplemented by a herbarium containing entire plants of the hundred weeds, and a cabinet containing their seeds or fruits, and will be followed by others.

IN the *Bulletin*, No. 3 (Petroleum Series), issued by the School of Mines, University of Wyoming, Mr. W. C. Knight gives an account of the oil-fields of Crook and Uinta counties. The geological features of the oil-yielding districts are briefly sketched and illustrated by maps and sections in the text. Tables showing the results of testing in various samples of oil are contributed by Mr. E. E. Slosson.

"NOTES on some Jurassic Plants in the Manchester Museum," by Mr. A. C. Seward, are published in the *Memoirs* of the Manchester Literary and Philosophical Society, vol. xliv. 1900, and reprinted in "Notes from the Manchester Museum," No. 6. The collection dealt with includes the plants figured by Lindley and Hutton, in addition to other specimens in the museum. The synonymy of numerous species is given, and a list of Inferior Oolite plants contained in the museum collections is also added. These notes are accompanied by four well-executed plates and a useful bibliography.

IN the *Mémoires du Musée Roy. d'Hist. Nat. de Belgique*, t. i. 1900, Mr. Seward describes the Wealden flora of Bernissart (Belgium). The plants described are obtained from a freshwater deposit and are of a fragmentary nature; the flora is remarkable for the relatively large number of ferns included, while the cycads are absent and the conifers rare. Twenty species of plants are recognised, more than half of which are known also from England and Germany. The memoir is well illustrated by four plates and several text-figures.

SINCE the publication in our last number of a list of forthcoming science books, we have received the list of announcements of Mr. Gustav Fischer, of Jena. It is as follows:—"Atlas der topographischen Anatomie des Menschen," by Profs. Bardeleben and Haeckel, Zweite völlig umgearbeitete und vermehrte Auflage; "Organographie der Pflanzen, insbesondere der Archegoniaten und Samenpflanzen," by Prof. Goebel, Zweiter Teil, 2 Heft, Erster Teil; "Klinisches Jahrbuch," Siebenter Band, Funftes Heft; "Lehrbuch der vergleichenden Anatomie der wirbellosen Tiere," by Prof. A. Lang, Zweite umgearbeitete Auflage, Erste Lieferung, Mollusca; "Die Grundlagen und die Methoden für die mikroskopische Untersuchung von Pflanzenpulvern," by Prof. A. Meyer; "Aetiologie und Prophylaxe der Lungentuberkulose," by Dr. J. Ruhemann; "Anatomisch-klinische Vorträge aus dem Gebiete der Nervenpathologie," by Prof. K. Schaffer; "Praktikum der physiologischen Chemie," by Prof. Fr. N. Schulz; "Lehrbuch der Histologie und der mikroskopischen Anatomie des Menschen mit Einschluss der mikroskopischen Technik," by Prof. P. Stoehr, Neunte verbesserte Auflage; "Das Neuron in Anatomie und Physiologie," by Prof. Max Verworn.

Mr. H. K. Lewis promises the following new books:—"Blood and Blood Pressure," by Dr. G. Oliver; and new editions of "Hygiene and Public Health," by Dr. Louis Parkes: "Medical Electricity," by Dr. Lewis Jones; "The Student's Medical Dictionary" and "A Pocket Medical Dictionary," by Dr. G. M. Gould.

Messrs. Lovell Reeve and Co., Ltd., have in preparation a "Monograph of the Membracidæ," by G. B. Buckton, F.R.S., who will be glad to hear, through the publishers, from entomologists and others as to specimens which they have reason to believe are as yet unknown to science.

Messrs. Williams and Norgate announce:—"The Opus Majus of Roger Bacon," edited with introduction and analytical table by J. H. Bridges.

MR. MARTINUS NIJHOFF, bookseller, of the Hague, has just issued the first part of his classified natural science catalogue containing nearly 2500 entries.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Lieut. Sullivan; a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Mr. J. E. Matcham; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Mr. R. G. Pointer; a Vulpine Phalanger (*Trichosurus vulpecula*) from Australia, presented by Miss Bartlett; a Blue-faced Amazon (*Chrysotis versicolor*) from St. Lucia, West Indies, presented by Miss M. Moon; two Greek Tortoises (*Testudo graeca*), European, presented by Sister Heather Grey; a Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mrs. E. Putz; a Bonnet Monkey (*Macacus sinicus*) from India, two Pucheran's Guinea Fowls (*Guttera pucherani*) from Somaliland; a Large Grieved Tortoise (*Podocnemis expansa*) from the Amazons; a Greek Tortoise (*Testudo graeca*), European, deposited; two Common Rattlesnakes (*Crotalus durissus*), two Water Vipers *Ancistrodon piscivorus*), two Copper-head Vipers (*Ancistrodon contortrix*), two Mocassin Snakes (*Tropidonotus fasciatus*), a Hog-nosed Snake (*Heterodon platyrhinos*) from North America, received in exchange.

## THE STABILITY OF A SWARM OF METEORITES AND OF A PLANET AND SATELLITE.

THE problem of the stability of a swarm of meteorites which is under the action of its own gravity and the attraction of the sun, that is to say the determination of the condition under which the swarm will remain unbroken up by the tidal action of the sun, has been dealt with by Schiaparelli, M. Luc Picard and M. Charlier (*Bulletin de l'Académie de St. Petersbourg*, t. xxxii. No. 3). The result obtained by the first assigns a much wider limit of stability to such a system than that arrived at by the other two investigators mentioned; but there cannot, I think, be any doubt of the greater correctness in actual cases of the narrower limit. The problem is intimately related to the still more interesting question of the stability of the earth-moon system, which was treated by Mr. G. W. Hill in a remarkable paper in the *American Journal of Mathematics* for 1878. This again is, in another form, the problem treated still earlier with a special object in view by Edouard Roche (*Mém. Acad. de Montpellier*, vol. i. 1847–50; see also *Annales de l'Observatoire*, t. v.), when he arrived at his result concerning the limiting relation between the distance of a satellite from a primary and the diameter of the primary, which must hold in order that the satellite, held together by its own gravitation only, may just not break up under the tidal forces due to the primary, and his corresponding result for a planet's or satellite's atmosphere.

These investigations, though of great general interest, are not so well known as might be expected, and one object of this paper is to give some slight account of them. An abstract of the work of Charlier and Hill is given also in Dr. Routh's recently published work on "Dynamics of a Particle." But I wish also to point out how the main conclusions of Charlier, that of Roche with respect to a planet's atmosphere, and more indirectly the result of Hill, can be obtained by means of elementary considerations.

The problems just referred to have been treated by very different methods. Schiaparelli's discussion is a direct attack of a somewhat long and involved nature; those of MM. Picard and Charlier (*Bulletin de l'Académie de St. Petersbourg*, t. xxxii. No. 3; see also Tisserand, *Mécanique Céleste*, t. iv.) make use of the method of revolving axes. The radius vector from the centre of the sun to the centre of the meteoric swarm is supposed to revolve with angular velocity, $n$ say, about the centre of the sun as a fixed point; then the motion of a particle of the swarm is referred to three directions at right angles to one another having their origin at the centre of the swarm, and turning with the radius vector just specified. These axes may be taken as an axis of $\xi$ towards the sun, an axis of $\eta$ at right angles to this in the plane of motion of the centre, and an axis of $\zeta$ at right angles to this plane. Then equations of motion relative to these moving axes are written down for a particle the component distances of which from the centre are $\xi, \eta, \zeta$, it being supposed in the first place that the distance $r$ of the centre of the swarm from the sun, and the angular velocity $n$ of the radius vector are both variable. Approximate values of the forces are obtained by supposing that $\xi, \eta, \zeta$ are small in comparison with $r$, and that $r$, and therefore also $n$, is constant. When account is taken of the condition that must hold for the central particle, the equations assume the very simple form

$$\ddot{\xi} - 2n\dot{\eta} - (3n^2 - \mu)\xi = 0, \quad \ddot{\eta} + 2n\dot{\xi} + \mu\eta = 0, \quad \ddot{\zeta} + (n^2 + \mu)\zeta = 0.$$

The value of $\mu$ is $\frac{4}{3}\pi ks$, where $k$ is the gravitation constant and $s$ is the average density of the portion of the swarm within the spherical surface on which the particle lies, supposed symmetrical about the centre. Considering only particles in the plane of $\xi, \eta$, the values of these co-ordinates are supposed to oscillate about certain constant values, so that $\xi = a \cos(\omega t + \epsilon)$, $\eta = b \sin(\omega t + \epsilon)$. That is, each particle is supposed to revolve in an ellipse, the centre of which is the centre of the swarm, and of which one axis is along the line of centres and the other perpendicular to that line. The ellipse is a circle if $a = b$, and $\omega$ is then the angular velocity of the *relative* motion of the particle about the centre. These values substituted in the first two equations of motion lead to the condition

$$(\omega^2 - \mu)(\omega^2 + 3n^2 - \mu) - 4\omega^2 n^2 = 0.$$

Now $\omega$ is $2\pi f$, if $f$ be the frequency of oscillation; and if the oscillation be stable, $f$ will have a positive real value. The roots of the quadratic in $\omega^2$ just written must therefore be real and positive; and it is not hard to see that the required condition for this is $\mu > 3n^2$. This gives, when $\mu$ is replaced by $\frac{4}{3}\pi ks$, and $n^2$ by $kM/r^3$, where M is the mass of the sun (for we have for the central particle $n^2 r \doteq kM/r^2$), the inequality

$$\tfrac{4}{3}\pi s r^3 > 3M.$$

*In order, therefore, that the swarm of small particles may keep together, it is necessary that its average density be greater than that of a spherical distribution of matter of radius equal to the sun's distance and of three times the sun's mass.* The problem for an elliptic orbit of eccentricity $e$ has been considered by M. Callandreau (*Bulletin Astronomique*, 1896). The condition $\mu > 3n^2$ is in this case replaced by $\mu > 3n^2 + 5e^2n^2$. The swarm is therefore rendered less stable by the eccentricity.

It is to be remembered that the effect of the distortion of the swarm by the tidal force of the sun is neglected, and it does not seem of much importance to consider eccentricity of orbit so long as the assumption of sphericity of figure is maintained.

Since the equation of condition stated above must be satisfied, only values of $\omega$ consistent therewith, and with the inequality $\mu > 3n^2$, are admissible. Thus if $\omega = 0$, that is if there be no revolution of any particle about the centre of the swarm, the equation gives $\mu = 3n^2$, and the inequality is not fulfilled. This is a limiting case between stability and instability.

Now let the differential equations of motion referred to above (from which the more roughly approximate equations quoted are derived) be modified for the case in which the swarm is replaced by a planet of given mass $m$, and the particle considered by a satellite of mass $m'$ at the external point $\xi, \eta, \zeta$, then let them be multiplied by $\dot{\xi}, \dot{\eta}, \dot{\zeta}$ respectively, integrated, and added. Thereby will be obtained the equation of kinetic energy for the relative motion, commonly called Jacobi's equation. This has, if $\dot{\xi}^2 + \dot{\eta}^2 + \dot{\zeta}^2$, the square of the resultant relative velocity, be denoted by $v^2$, the form

$$v^2 - \left[ 2\frac{\mu}{\rho} + 2\frac{r^2 n^2}{r_1} + n^2 \left\{ (r - \xi)^2 + \eta^2 \right\} \right] + C = 0$$

where

$$\mu = k(m + m'), \; \rho = \sqrt{\xi^2 + \eta^2 + \zeta^2}, \; r = \sqrt{(r - \xi)^2 + \eta^2 + \zeta^2},$$

C is a constant, and $r$ is, as before, the distance of the centre of the sun from that of the planet.

Now when $v^2$ has a given value, the satellite must have its centre on the surface of which the equation is obtained by placing that value in the equation just written. Hence, since $v^2$ is positive, the satellite cannot pass across the surface for which $v^2 = 0$, that is the surface for which

$$2\frac{\mu}{\rho} + 2\frac{r^3 n^2}{r_1} + n^2 \left\{ (r - \xi)^2 + \eta^2 \right\} - C = 0;$$

by putting $\zeta = 0$ in this we obtain the equation of the curve in which the surface intersects the plane of $\xi, \eta$. An investigation of the surface shows that if C be positive the surface consists of three sheets, of which two are closed and surround the sun and the planet respectively; and the third is asymptotic to a surface of revolution about an axis passing through the sun's centre perpendicular to the ecliptic, and surrounds the two closed surfaces. Within the closed surfaces, or outside the third surface, $v^2$ is positive; between the closed surfaces and the outer asymptotically cylindrical surface $v^2$ is negative, and therefore $v$ is imaginary. The satellite must therefore be within one of the closed surfaces, or beyond the outer surface; in either case it cannot cross the surface of zero velocity.

When the proper values of the quantities for the earth-moon system are inserted, it is found that the moon is within the closed sheet surrounding the earth, from which, therefore, it cannot escape. The distance of the moon's centre from the earth, Mr. Hill has calculated, cannot exceed 109·694 equatorial radii of the earth. The result is based, of course, on the assumption that the eccentricity of the earth's orbit may be neglected.

If, besides neglecting the eccentricity, we suppose the moon to move in the plane of the ecliptic, and to be so distant that we may neglect terms in $\eta$, the equation of the curve of no velocity in the plane of the ecliptic is

$$\frac{\mu}{\rho} + \frac{3}{2}n^2\xi^2 = c,$$

or if $\xi = \rho\cos\theta$

$$3n^2\cos^2\theta . \rho^3 - c\rho + 2\mu = 0,$$

where $c$ is another constant.

The roots of this cubic in $\rho$ are all real if $\cos^2\theta > c^3/81n^2\mu^2$, and the rule of signs shows that there is only one negative root. The curve of no velocity consists then of a closed branch round the origin of co-ordinates, the centre, E, of the earth in the present case. Besides this there are two infinite branches which are asymptotic to the parallel lines AB, A′B′ represented by

$$3n^2\xi = c.$$

Thus the curve is as roughly represented in Fig. 1. The line CD shows the direction of the radius vector from the sun.

Between the closed curve and the infinite branches $v$ is imaginary, and the satellite must be either within the closed branch or beyond the boundary represented by the infinite branches. The calculation gives very approximately 110 equatorial radii of the earth for the greatest distance of any point of the closed branch from the centre. The form of this branch is that of an oval, being slightly longer in the direction towards the sun than in the transverse direction.

The theorem of Roche which we discuss here is contained in the statement that the atmosphere of a satellite cannot be held together merely by the gravitational attraction of the satellite unless the inequality

$$\frac{m}{M} > (2+c)\frac{a^3}{r^3}$$

is fulfilled, in which $m$ is now the mass of the satellite, M that of the planet, $c$ the ratio of the square of the angular velocity of the satellite's axial rotation to the square of the angular velocity of its orbital revolution, $a$ denotes the satellite's radius, and $r$ the distance of the centre of the satellite from the planet. If the densities of the planet and satellite be $s_1, s$, and their radii $a_1, a$, and $c$ be unity, that is if the satellite turns always the same face to the primary, we have for the inequality

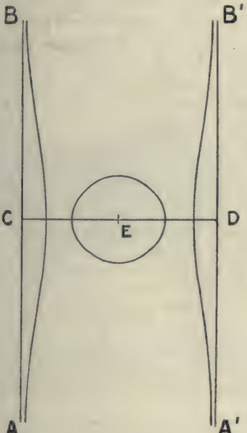

FIG. 1.

$$\frac{r^3}{a_1^3}\frac{s}{s_1} > 3, \text{ or } r > 1{\cdot}44a_1\sqrt[3]{s_1/s}.$$

It should be mentioned that Roche's investigations embraced much more than this; they included the determination of the figure of a fluid satellite, and entered into other matters which cannot be discussed here.

To deal with these questions in an elementary way, consider the important particular case of a spherical swarm of radius $a$ moving round the sun, and turning as a whole about an axis perpendicular to the orbit in the period of revolution, so that it turns the same face always towards the sun. This is, of course, a less general problem than that considered above; it is indeed the case of that problem in which $\omega$ is zero It is interesting to see from the more general investigation that the condition obtained by the consideration of this case is sufficient to give stability for any value of $\omega$ provided it fulfils the equation of condition stated above. We shall obtain also by the elementary process a wider condition for the case in which $\omega$ is not zero. This will give the inferior limit assigned by Roche to the distance of a satellite from its primary.

A particle, of unit mass, say, at the centre, C (Fig. 2), at distance SC ($=r$) from the sun, is in relative equilibrium under the sun's attraction and the so-called centrifugal force. That is, we have for that particle

$$\frac{kM}{r^2} - n^2r = 0.$$

Again, a particle on the outside of the swarm at the point nearest the sun is at a distance $r-a$, and under attraction $kM/(r-a)^2$. Hence there is a preponderance of attraction over the acceleration $n^2(r-a)$ towards S. This excess is

$$\frac{kM}{(r-a)^2} - n^2(r-a) = kM\left\{\frac{1}{(r-a)^2} - \frac{1}{r^2} + \frac{a}{r^3}\right\}$$
$$= 3kM\frac{a}{r^3}$$

nearly. This must at least be balanced by the attraction towards the centre, C, exerted by the swarm, if the particle is not to leave the swarm. Hence we must have $\frac{4}{3}\pi ska^3/a^2 > 3kMa/r^3$, or

$$\tfrac{4}{3}\pi sr^3 > 3M,$$

as before. The same result would be obtained for a particle at B. In that case the attraction of the sun $kM/(r+a)^2$ would be insufficient to supply the acceleration $n^2(r+a)$ towards the sun. The condition that this should be supplied by the attraction of the swarm is that $\frac{4}{3}\pi sr^3$ should be at least equal to 3M.

This result holds, of course, for all particles within the swarm on the line SC, for no particle experiences any force on the whole from the spherical layer outside it.

It is to be observed that a particle at A or B (or on the line SC) is in greater danger of leaving the swarm from the causes just explained, than a particle elsewhere on the spherical surface.

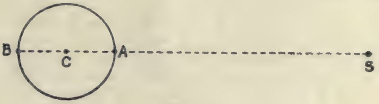

FIG. 2.

If the particles of the swarm have other angular velocities than that supposed above about an axis through its centre perpendicular to the plane of the orbit, the investigation will run as follows. Suppose applied to each of the particles a force per unit mass equal and opposite to that, $n^2r$, exerted by the sun on the central particle. This will have no effect on the relative motions of the particles or on the figure of the swarm. Upon the particle nearest the sun the force per unit mass toward the sun is now

$$\frac{kM}{(r-a)^2} + \omega_1^2a - n^2r = 2kM\frac{a}{r^3} + \omega_1^2a$$

if $\omega_1$ be the angular velocity *in space* of the radius vector drawn from the centre to the particle (that is, not the relative angular velocity $\omega$ above, but $\omega + n$). This must at least be balanced by the attraction towards the centre exerted by the swarm if the particle is not to leave it. Thus we have $\frac{4}{3}\pi ksa > 2kMa/r^3 + \omega_1^2a$, or since $kM = n^2r^3$

$$\tfrac{4}{3}\pi sr^3 > \left(2 + \frac{\omega_1^2}{n^2}\right)M.$$

Thus if the swarm as a whole make one rotation in the period of revolution round the sun, $\omega_1^2/n^2 = 1$, and we obtain the same result as before.

Let now the swarm of particles be replaced by a spherical planet with an atmosphere composed of discrete small particles, the whole being held together by gravitational attraction alone. Then if the mass of the planet be denoted by $m$, the inequality $\frac{4}{3}\pi sr^3 > 3M$ becomes $\frac{4}{3}\pi sa^3 > 3Ma^3/r^3$, that is $m/M > 3a^3/r^3$. This is to be fulfilled if the atmosphere is not to be dissipated by tidal action. The same thing will, of course, hold for a primary and the atmosphere of a satellite.

In the more general case, that in which the satellite has rotational velocity $\omega$ about its axis (supposed perpendicular to the plane of the orbit), we have, assuming that the satellite is spherical and denoting $\omega_1{}^2,/n^2$ by $c$, $m/\mathrm{M} > (2+c)a^3/r^3$. This agrees with the former result when $c=1$. These results were first obtained by M. Roche.[1]

The figure of a fluid satellite is determined by finding a surface to which the resultant of the gravitational pull of the primary on unit mass, a force $n^2r$ equal and opposite to the gravitational pull on unit mass at the centre, the gravitational force per unit mass exerted by the matter of the satellite itself, and the centrifugal force of unit mass, is everywhere perpendicular. A first approximation to the force due to the satellite itself is obtained by neglecting the deviation from sphericity, as is done above. But into this discussion we cannot here enter. It can only be stated that the final result, taking into account the distortion of the satellite, is that the satellite will be broken up if it approaches closer to the primary than the limit given by the inequality

$$r > 2{\cdot}44 \sqrt[3]{s_1/s_1}.$$

Now imagine a planet and a satellite moving round the sun, the satellite being destitute of relative velocity. The satellite may, for example, be regarded as a particle (of unit mass say) of a ring of small mass composed of particles surrounding the primary at a distance $a$, the whole turning, if that were possible, with angular velocity equal to that of the primary round the sun. By what we have seen above, the excess of solar attraction over the sunward acceleration is, for a particle on the side nearest the sun, $3k\mathrm{M}a/r^3$. This must be balanced by the attraction $km/a^2$, so that we have the equality $km/a^2 = 3k\mathrm{M}a/r^3$.

From these expressions for the forces we see that the potential energy, with a term for centrifugal force included, may be taken, for unit mass of the infinitesimal satellite on the line of centres at the point nearest the sun, as $-km/a - \frac{3}{2}k\mathrm{M}a^2/r^3$. This is an example of the almost self-evident principle, known as the theorem of Coriolis, that if there be included a term in the potential energy which will give the components of centrifugal force, we may write down the equation of relative kinetic energy, just as if the rotating axes were fixed. The potential energy thus required for the centrifugal force on a particle of unit mass at a point at distances $\xi$, $\eta$, $\zeta$ from the planet's centre, measured respectively along the line of centres, perpendicular to this line in the plane of motion, and perpendicular to the plane of motion, is $-\frac{1}{2}n^2\{(r-\xi)^2+\eta^2\}$, or, since $n^2r = k\mathrm{M}/r^2$,

$$-\tfrac{1}{2}k\mathrm{M}\{(r-\xi)^2+\eta^2\}/r^3.$$

The total potential energy being taken as

$$-\left[\frac{km}{\rho} + \frac{k\mathrm{M}}{r_1} + \frac{1}{2}\frac{k\mathrm{M}}{r^3}\left\{\left(r-\xi\right)^2 + \eta^2\right\}\right]$$

(with, as before,

$$v^2 = \dot{\xi}^2 + \dot{\eta}^2 + \dot{\zeta}^2,\ \rho^2 = \xi^2 + \eta^2 + \zeta^2,\ r_1{}^2 = (r-\xi)^2 + \eta^2 + \zeta^2,$$

and $n^2 = k\mathrm{M}/r^3$), the equation of relative kinetic energy is

$$\frac{1}{2}v^2 - \left[\frac{km}{\rho} + \frac{k\mathrm{M}}{r_1} + \frac{1}{2}\frac{k\mathrm{M}}{r^3}\left\{\left(r-\xi\right)^2 + \eta^2 + \zeta^2\right\}\right] + \mathrm{C} = 0,$$

which, for an infinitesimal satellite, is Hill's equation as given above.

For the moon, which has mass $m'$ sensible in comparison with the mass, $m$, of the earth, the first term in the square brackets should be $k(m+m')/\rho$.

It may be noticed by the dynamical student that if the above expression for the potential energy be denoted by V, we have not $\ddot{\xi} = -\partial\mathrm{V}/\partial\xi$, &c., for the equations of motion, but

$$\ddot{\xi} - n\eta = -\partial\mathrm{V}/\partial\xi,\ \ddot{\eta} + n\xi = -\partial\mathrm{V}/\partial\eta,\ \ddot{\zeta} = -\partial\mathrm{V}/\partial\zeta.$$

A. GRAY.

---

[1] I have found since the above was written that the same elementary view of this matter is given by Roche himself in his paper "Recherches sur les Atmosphères des Comètes," *Annales de l'Observatoire*, t. v. 1859. Perhaps I may here direct attention to a valuable paper by Roche (which may, however, though I have not seen it referred to, be well known to astronomers), entitled "Essai sur la Constitution du Système Solaire," *Mém. de l'Acad. de Montpellier*, t. viii. This gives a general account of the author's cosmogonic researches.

## *ANTELOPES AND THEIR RECOGNITION MARKS.*

THE Tragelaphine Antelopes hold a unique position amongst the hollow-horned ruminants. No other group can show species so sharply contrasted in size and build as the massive eland rising over sixty inches at the withers, and the dainty little bush-buck which falls short of half that height. Only the Indian black buck amongst the gazelles can match the nylghaie and nyala for diversity of sexual colouring; and for elegance of form, coupled with beauty of marking and grandeur of carriage, the kudu is surpassed by no species of mammal.

Apart from certain features presented by the skull and horns, the affinity between the species here mentioned is attested by the markings of the skin. On a ground-colour shading from slate to chestnut are distributed certain white spots, patches or stripes, which crop up so persistently in the different genera as to leave no doubt they are a heritage from a common ancestor. A comparison between the skins of the existing species suggests that this ancestor was coloured somewhat as follows:—Body and head yellowish red; flanks and hind-quarters striped with white; on the throat two white patches, one at each end; one or two spots on the cheeks, a V-shaped stripe between the eyes, a white chin, a white upper lip; legs paler on the inner side, quite white at base close to chest and groin, and with two white spots on the pasterns in front.

Some or all of these markings have been inherited with scarcely an exception by every known species of Tragelaphine. Sometimes the spots on the head, sometimes the stripes on the body, sometimes the patches on the throat are suppressed; but even in extreme cases of suppression, a spot here, a stripe there, persists as a tell-tale sign of descent. The usefulness of characters so constant may be taken for granted. The nature of their usefulness has been discussed by both Wallace and Darwin; but so great is the discord between the opinions of these authorities that one cannot think both are right.

Referring to the importance of special marks for recognition where many species of nearly the same size and general form inhabit the same region, Mr. Wallace says: "It is interesting to note that these markings for recognition are very slightly developed in the antelopes of the woods and marshes. . . . The wood-haunting bosch-bok (*T. sylvaticus*) goes in pairs, and has hardly any distinctive markings on its dusky chestnut coat, but the male alone is horned. The large and handsome kudu frequents brushwood, and its vertical white stripes are no doubt protective, while its magnificent spiral horns afford easy recognition. The eland, which is an inhabitant of the open plain, is uniformly coloured, being sufficiently recognisable by its large size and distinctive form; but the Derbyan eland is a forest animal, and has a protectively striped coat. In like manner, the fine Speke's antelope, which lives entirely in the swamps and among reeds, has pale vertical stripes on the sides (protective), with white markings on face and breast for recognition" ("Darwinism," p. 220).

It may be inferred from this passage that the interest attached to the slight development of recognition marks in the antelopes of the woods and marshes lies in the needlessness of such marks for species living apart and not herding with others of the same general size and form. If, however, there is no likelihood of confusion, it is not quite clear from what species the horns of the kudu serve to distinguish their owner, nor what significance in this connection is to be attributed to the occurrence of horns only in the male of the bosch-bok. Similarly, it is not clear what use Speke's marsh-buck can have for recognition marks. If, however, the spots on the face and throat subserve recognition in this species, we must also conclude they are retained for that purpose in the bongo (*T. euryceros*), the lesser kudu, the nyala (*T. angasi*), in which they are very conspicuous, as well as in the various smaller kinds of bush-buck, which in other parts of Africa live the same life as the bosch-bok of the Colony. Surely, too, Derby's eland is at least as recognisable by its large size and distinctive form as the Cape species; yet it is adorned with a conspicuous V-shaped stripe between the eyes, and the lower throat-patch forms a white collar, standing boldly out against the black hue of the neck.

In short, if the marks in question have been preserved for recognition, it is singular that they are exceptionally well developed in the species that live in pairs or small parties by themselves in thick bush—species which, according to the hypothesis, have little, if any, need of them. It is conceded, of course, that the spots on the head and throat, like the stripes on the body, patches on the rump or any other visible external feature, including large ears, may, if required, serve as marks of identity; but in the case of the Tragelaphines, at least, it is hard to believe that that is any more their primary function than it is the primary function of large ears.

A mass of evidence can be brought forward in favour of Wallace's view that the body-stripes of these antelopes are protective; but there appear to me to be equally strong reasons for classifying the face and foot markings in the same category, and for regarding them as representing spots or streaks of sunlight passing through foliage or reflected from leaves.

It is possible, perhaps probable, that the other white patches on a typical Tragelaphine serve the same end; but their situation forcibly suggests that they have a still deeper significance. I believe they come within the scope of Thayer's hypothesis of concealment by the counteraction of light and shade. A convex body stands out amid surroundings of its own colour on account of the contrast between the light that is reflected from its upper surface and the shadow that pervades it below. Take away the light by darkening the upper side and the shadow by lightening the lower, and the body will vanish from sight with the destruction of its visible shape. By applying this principle to a typically marked Tragelaphine, the lesser kudu for example, it will be seen that the white is laid on where shadows are thrown; that the white rim on the upper lip and the white chin must counteract the shadows caused by the fold of the mouth and by the muzzle; the two white blotches on the neck must counteract the shadows thrown by the head and by the curvature of the throat, and the shadows cast by the breast and groin must be similarly obliterated by the white patches on the inner side of the base of the limbs.

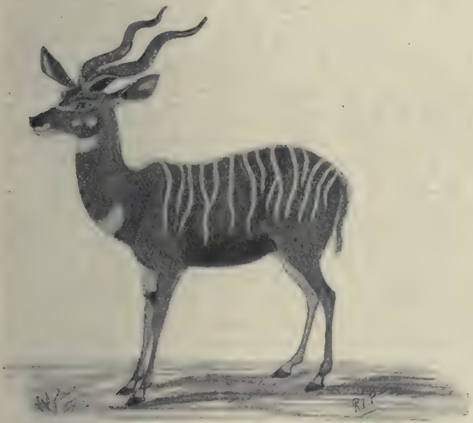

FIG. 1.—The Lesser Kudu, ♂.

That the white patches must have the effect here assigned to them will be obvious, I think, to any one who, with Thayer's hypothesis in mind, looks at a lesser kudu when it is standing full-face. The reason for the presence of marks concealing the animal from this point of view will be referred to later on.

If the markings of the Tragelaphines have the significance here attached to them, they should be better developed in the species that live in the bush than in those that frequent the open. Let us see in a few cases to what extent they are correlated with habit. Two well-marked species of eland live in Africa, to wit, Derby's eland (*T. derbianus*) from Senegambia and the commoner form (*T. oryx*) which, with its subspecies, ranges throughout the whole of East and South Africa. The former, according to Winwood Reade, "lives in the forest, and never of its own accord enters the plain." It is reddish in colour, with a black neck, a white collar, eye-stripes and many white stripes on the flanks and hind-quarters. Of the common eland the typical "dun coloured" desert form is, according to Selous, "particularly plentiful in the dry desert country through which the Chobe runs," and examples "from the Kalahari desert have no sign of a stripe." Farther to the north, both in Angola, South-east and East Africa, this unmarked type is replaced by its ancestral form, Livingstone's eland, which in colour and habits is intermediate between the Cape and Senegambian species. The skin is always marked with narrow white stripes, and the V-shaped mark between the eyes is often present. In British East Africa this eland, according to Jackson, was found in "sparsely timbered country and open bush bordering the plain rather than the plains themselves," and in Angola (Penrice) "it seems most partial to a thinly timbered country." There is thus a complete gradation from the strongly marked forest species through the weakly marked species frequenting the open bush to the unmarked desert species.

Take again the kudus. Both the species are well marked with white stripes on body and head, but the smaller (*S. imberbis*) is much more strikingly marked than the larger (*S. strepsiceros*), having more stripes on the body and two patches on the throat. In Somaliland, where both species occur, the larger lives, according to Swayne, in the mountains, on very broken ground where there is plenty of bush; and sometimes indeed ventures into the open plain (Inverarity). The lesser kudu, on the contrary, "is found in thick jungles . . . especially where there is an undergrowth of the slender pointed aloe which grows from four to six feet high" (Swayne). Both Swayne and Inverarity, moreover, bear witness that this species will allow a hunter to get within a few yards before dashing away—a notorious habit with protectively coloured animals. Evidence of a like kind is furnished by other species of Tragelaphines. The beautifully marked nyala (*T. angasi*) and bongo (*T. euryceros*) live in dense thickets; and the lovely little bush-bucks (*T. sylvaticus*, *scriptus*, &c.) seldom venture out of cover except at night-time to feed. On the other hand, the nylghaie, an aberrant member of the same tribe, is without body-stripes, and lives for the most part in more or less open country in India, and is not a typical denizen of the thick jungle at all.[1]

Further evidence on this head is supplied by another set of facts. Ungulates which live in thickets or rough ground affording cover to enemies have larger ears and a keener sense of hearing than those of the plains or high mountains where intruders have little chance of concealment. Note the small ears of the camel, a typically desert form; or of goats and sheep which from the mountain peaks can sweep the surrounding country for miles with their eyes and seek safety in flight long before the foe gets within ear shot. Compare also the small equine ears of Burchell's zebra, which herds in the open plain free from obstacles to interfere with vision, with the longer asinine ears of the mountain zebra which frequents rocky broken ground well fitted for the hiding of carnivores. In all the brilliantly marked Tragelaphines the ears are long and expanded, but in the nylghaie, and especially in the common eland, they are short and narrower. Indeed, one of the chief structural differences between Derby's eland and the Cape species is found in the size of the ears.[2]

The co-existence of white marks with long ears and a bush-life bears out the supposition that the marks, like the ears, are primarily for protection, and that if subservient to purposes of recognition they are merely of secondary importance in that capacity.

I strongly suspect, too, that the markings of the sable, roan, gemsbok and bontebok are for concealment, and not for recognition as Mr. Wallace supposes. The theory of recognition marks as applied to these antelopes assumes the need of some patch or spot to enable the members of a species to identify their own kind amongst the herds of other sorts living in the same place. The theory would rest upon a securer basis, if it could be shown that closely allied species feed together. But nothing, I suppose, is more certain than that, as a very general, perhaps invariable, rule, closely allied and similar species are not found together. If, for example, the gemsbok and the beisa lived side by side in the Kalahari, or Peters's palla and the common species in Rhodesia, there would perhaps be strong reasons for thinking that the differences in the facial bands, which enable us to recognise these species apart, serve the same end where the antelopes are themselves concerned. But the gemsbok and the beisa, the common and Angolan palla, never cross each other's path. Again, in cases where the geographical areas of two forms, closely allied, but distinguishable by bands or patches, meet, the two forms frequently interbreed, and so falsify the contention that marks keep like to like.

---

[1] An apparent exception to the rule that the development of white stripes and spots is correlated with a jungle life is found in the Sitatunga and Speke's marsh-buck, which "live in vast reed beds and papyrus swamps, and only come into the open at night" (Selous). Yet the stripes fade away in the adults of both sexes. Why is this? Possibly because these animals depend for concealment, not so much upon coloration that harmonises with that of the vegetation, as upon a newly acquired and efficient habit of hiding under the water itself, with only the end of the nose jutting above the surface (Selous and Gedge).

[2] Compare in this connection the small ears of the orang with the large ears of the chimpanzee. The former lives a more arboreal and therefore safer life than the latter, which requires quick hearing to enable it to escape to the trees when feeding on the ground.

That ungulates of different sorts herd together is well known; we read, for example, of zebras, gnus, pallas, spring-boks and buffaloes feeding in each other's company on the veldt. But so distinct from each other in form are these animals and others that might occur with them, that it is rating their visual powers very low—much lower, indeed, than our own—to hold that they require special patches to keep them from committing the errors of identification which the hypothesis assumes they are liable to fall into. I believe, then, that the need for recognition marks in the case of antelopes has been much over-rated,[1] and is too slight to warrant the belief that the facial and other stripes of, say, the gemsbok or sable have been perfected by their usefulness as such. On the other hand, when we see that the pattern of the zebra is for concealment, that the network of white stripes on the giraffe blends with the lights passing through the intercrossing branches of trees, that the colour and shape of the feeding hartebeest are like those of the ant-hills, all these and other facts attesting the importance of concealment, we are justified in suspecting that the white blaze of the bontebok and the facial bands of the gazelles and oryxes are developed for concealment and not for recognition.

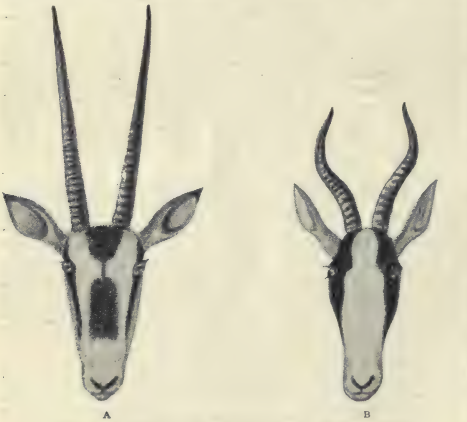

Fig. 2.—A, Face of the Beisa; B, face of the Bontebok.

The markings take the form of strongly contrasted bands of white and black, or brown. Objects banded in this way are, as a rule, more, and not less, difficult to see in their natural surroundings than those that are uniformly coloured. There is little of the gloss on the coat of a grey or white horse that is seen on a bay or black, because white hair reflects the light less vividly than dark. Hence alternating bands of these hues impart a blurred irregular aspect to a body, destroy the apparent evenness of its surface and break up the continuity of its outline. In an uncertain light a zebra's stripes[2] "merge into a grey tint," and mutually counteract each other, so that the animal is nearly invisible.

The stripes on the head of a gemsbok or sable are in a general way so like those on a zebra's coat that they must, one would think, have the effect of making the head inconspicuous. To explain the prevalence of such marks upon the head and fore-part of the body, of which the quagga furnishes an illustration, the following suggestions may be made.

Once aware of an enemy's presence, an antelope has three chances of escape—concealment, flight and self-defence. Concealment is often the wisest course to pursue, especially where females and young are concerned. For concealment perfect stillness is of all things most important. Movement means detection, and detection may mean death. But it is necessary at the same time for every movement of the enemy to be scrutinised, so that the right moment for flying may be seized, when the necessity for flight becomes apparent. For this purpose the face must be turned towards the enemy and both eyes be kept upon him. In this watchful attitude little of the foreshortened body is visible from the enemy's point of view, and if the head of the antelope be carried low with the nape in a line with the spine, practically nothing of the animal is exposed but the head and the fore-legs. Hence the special importance of protective markings on these parts.[1] Again, when lying on the ground the body will often be hidden by low scrub or, if cover be absent, may simulate a mound of earth or a termite's nest[2]; but the head, if protectively coloured, may with safety be raised to keep an eye on the surrounding country and guard against surprise.

The sexual colours of the Tragelaphines still remain to be touched upon. Darwin believed that the markings of the kudu, harnessed bush-buck, &c., were in the first instance acquired by the male, then intensified by sexual selection, and partially transferred to the female. Against this hypothesis may be urged the evidence already adduced in favour of their protective[3] value, and the distinctness they exhibit in the newly-born or even fœtal young. Nevertheless a difference of colour, small or great, but as yet unexplained, does exist between the males and females of all the species of the group. It is noticeable, too, that the deviation affects the male; that it takes the direction of nigrescence, but by no means always of beauty, and that the female adheres to the typical coloration of the group.

There is no evidence, so far as I am aware, that the assumption of a dark coat by the male is connected with any peculiarity in mode of life of this sex, which would attest its use for concealment. On the contrary, since the colour—at least, in the case of the nylghaie ("Descent of Man," p. 535)—becomes intensified at the breeding season, without the growth of new hair, and has its appearance arrested by emasculation, its significance appears to be purely sexual and the outcome or accompaniment of "male katabolism." If so, it may have been intensified and fixed by the exercise of choice on the part of the females, or by the destruction or expulsion of their paler, less vigorous rivals by the stronger and darker males, which thus secured the females for themselves and left the greatest number of offspring.

It is significant that the three species of antelopes, namely the nyala, the nylghaie and the Indian black buck, in which the sexes differ strikingly from each other—differ indeed to an extent that is equalled by few species of mammals and surpassed by none—the female is without horns or other weapons of defence. This defencelessness, coupled with the exigencies of maternity, has compelled an adherence on her part to the normal protective coloration of the group; whereas the males, powerfully built and strongly horned, have been able to dispense to a great extent with colours that harmonise with those of the environment.

Warning characters are rare in mammals; but the difference in colour between the bull and cow of the species just mentioned may conceivably benefit the former at the expense sometimes of the latter by serving to distinguish him, the horned powerful fighter and dangerous antagonist when brought to bay, from her, the weak and defenceless one who may be attacked and pulled down with impunity. Why not?

R. I. Pocock.

---

[1] If the American prong-buck were an inhabitant of Africa, I presume that its conspicuous patterns, possibly indeed the unique shape of its horns, would be cited as evidence supporting the theory of recognition marks. But in the prairies of the United States there are no species that resemble it in size and form, so as to create confusion as to identity. The species furnishes a good instance of Thayer's principle.

[2] Mr. Wallace is surely "putting the cart before the horse" in the passage where he speaks of the coloration of the zebra as an instance of a style of marking for recognition becoming also protective.

[1] Presumably it is for an analogous reason that the tiger has a pair of sunlight patches on its face, so that its chances of concealment may be increased when watching for prey or creeping towards it.

[2] In the case of the gemsbok, beisa and some gazelles the black longitudinal stripe passing along the side may enhance this resemblance by representing the shadow that is often seen where a boulder or mound meets the soil. The darkening of the coat on this area of the body, such as is seen, for instance, in the Asiatic wild ass (Kiang), should have the effect of deadening the light reflected from the bulging flank.

[3] Here and elsewhere in this article I have purposely used the word "protective" as the equivalent of procryptic or celative, which are less familiar to general readers.

## GEOLOGY AT THE BRITISH ASSOCIATION.

THE geologists had a busy and profitable week at Bradford, and an air of business-like application to work pervaded their meetings from first to last. The programme ought to have been long enough to satisfy even the most devoted adherent of Section C; but apparently there was no sense of satiety, since on two or three occasions when it was proposed from the platform that communications should be taken as read, there were protests raised by the audience, who seemed determined to carry matters through with true North-country thoroughness, and wished to hear everything. And indeed it may be said that there was scarcely a paper in the long list which did not contain scientific matter well worthy of discussion, though it must be acknowledged that in several instances the matter was not particularly novel. It was only by the strict enforcement of a time-limit upon readers of papers and debaters, and by sessions on the mornings of Saturday and Wednesday as well as lengthy sittings on the other days of the meeting, that the business was got through. Under these circumstances it was inevitable that some excellent papers scarcely received full justice; but the discussions were nevertheless unusually full of vigour, and what was still better, entirely lacking in acrimony.

The fine weather of the week, which was so favourable to the short afternoon excursions, now a recognised and highly valued feature in the affairs of the section, had probably much effect in fostering the prevailing good-humour, while the personality of the president was a strong influence in the same direction, especially in the discussions.

To particularise all the papers within the space-limits of this article is impossible, and we can only attempt to convey a general impression of the proceedings, with brief reference to the points of main interest.

On Thursday, as a fitting appendix to the wide-reaching generalisations of the president's address, already printed in these pages, we had a series of papers from Prof. J. Joly dealing with geological problems from the standpoint of the physicist. In one of these, "On the geological age of the earth, as indicated by the sodium contents of the sea," Prof. Joly reiterated the calculations and conclusions which have recently attracted so much attention in geological circles; in another, "On the inner mechanism of marine sedimentation," he showed the chemical and physical reasons for the rapid precipitation of fine solid matter brought down in suspension by rivers into the sea; a third of kindred character gave the result of "experiments on denudation by solution in fresh and salt water"; and a fourth, which was especially attractive to the petrologists and mineralogists, dealt with "the viscous softening of rock-forming minerals at temperatures below their normal melting point," showing how certain minerals could be observed to attain a plastic state some time before actually melting.

At the same meeting Prof. W. B. Scott, of Princeton, gave a highly interesting account, with lantern illustrations, of recent explorations in Patagonia conducted under the direction of Mr. J. B. Hatcher. Besides correcting previous errors as to the age of the deposits, the records and the rich collections of fossils obtained by this expedition have sufficed to prove a close connection between Australia, New Zealand and South America in Miocene times, and in several other respects to modify profoundly our previous ideas of South American geology, and incidentally to show how much geologists have still to learn in every way from the unexplored tracts of the earth's surface.

On Friday, Prof. J. Milne led off in his usual happy vein with an account of the year's work of the Seismological Committee, and was followed by Mr. Clement Reid, who showed how well-chosen, from geological reasons, was the site for instrumental observation, by the same committee, of the Upway disturbance. There then followed a series of papers and reports on the Mountain-limestone district of north-west Yorkshire and its underground waters, Mr. S. W. Cuttriss giving an account of the adventurous exploration of the deep pot-holes and caves of this district by himself and other members of the Yorkshire Ramblers' Club, and the Rev. W. Lower Carter and Mr. A. R. Dwerryhouse presenting the results obtained by a local committee and by a committee of the Association in the investigation of the subterranean drainage of the limestone. Being well-illustrated by lantern slides, these papers besides attaining their more direct purpose served to give the strangers an idea of the general characteristics of the district which was afterwards to be visited by geological excursion parties. By the use of suitable chemical reagents the course of the water from its disappearance in "sink holes" of the limestone to its reappearance in springs at lower levels has in several instances been traced; it has been shown that the main direction of underground flow is along the master-joints of the limestone; and a subterranean watershed of which there is no indication at the surface has been traced for some distance. These experiments are to be continued, and a grant of 50*l*. was made by the Association towards this end.

Among other papers taken on Tuesday were two by Mr. E. Greenly, giving further results of his painstaking researches in Anglesey. In one of these he dealt with the ancient surfaces or peneplains which he thinks can be recognised in North Wales; the older plain he is inclined to regard as of sub-Carboniferous age, and the later as Mesozoic, possibly Cretaceous. There was an interesting discussion on this paper, in the course of which Mr. Greenly acknowledged that his views were only tentatively held, and might require modification. Dr. G. Abbott then gave an account of his investigation of the concretionary structures of the Magnesian Limestone of Durham, illustrating his subject by lantern-slides and the exhibition of a large series of specimens.

Saturday's business began with a paper by the President, "On a concealed coalfield beneath the London basin," in which it was urged, on data not altogether convincing, that if a boring were made in the vicinity of Enfield Lock on the Lea, it might be expected to reach Coal-measures. As a speaker in the discussion remarked, such a boring would no doubt reveal something interesting, but whether Coal-measures was another matter. Then followed a paper by Mr. R. H Tiddeman "On the formation of reef-knolls," which was practically a criticism of Mr. J. E. Marr's views as to the development of these structures in the Mountain-limestone of West Yorkshire and Lancashire by earth-movement, and a reiteration of the author's earlier contention that they were originally formed as mounds on a slowly sinking sea-bottom. As Mr. Marr was present to champion his own cause, the paper was followed by a brisk but friendly discussion, which was prolonged on a later day in the open air, when some of the mounds at Cracoe near Skipton were visited by a few members interested in the subject. No definite conclusion was reached, but the necessity for further investigation was made evident, and it was suggested that the truth might lie in a combination of the two hypotheses.

Another paper taken on Saturday was that of Mr. W. Gibson, "On rapid changes in the thickness and character of the Coal-measures of North Staffordshire," in which it was shown that the areas of maximum and minimum deposit in these rocks correspond respectively with a syncline and anticline, thereby suggesting that local areas of deposit were being marked out by contemporaneous movements of elevation and depression, thus fulfilling in North Staffordshire the conditions characteristic of the Carboniferous rocks of the Midlands generally. These results have an important practical application, inasmuch as the unexplored coal-field to the westward, which occupies a syncline, may thereby be expected to exhibit an increase in the thickness of the strata. At the same meeting, Rev. J. F. Blake brought forward some revolutionary suggestions in regard to the registration of type-specimens, among other proposals urging that a new class of "adopted" types should be recognised and registered where the original types were missing or inadequate, and that the type should consist of a single specimen. As Prof. Blake has now been elected a member of the committee of the Association at present in existence for furthering the registration of type-specimens, we may hope that his interest in the matter may bear fruit.

On Monday there was a crowded audience to hear the joint discussion with the botanists on the conditions during the growth of the forests of the Coal-measures. The discussion was opened by Mr. R. Kidston, who gave a succinct account of the plant-life of the period, illustrated by fine lantern slides. Mr. A. Strahan then dealt with the physical conditions, and gave his adherence to the "drift" as opposed to the "growth-in-place" theory of the origin of coal-seams, summing up the normal sequence of events in the formation of a seam as follows:—First, the outspreading of sand and gravel with drifted plant remains; followed by shale as the currents lost velocity; and then a growth of presumably aquatic vegetation in extremely shallow water into which wind-borne vegetable dust and floating vegetable matter was carried; after which renewed subsidence brought in the sand and mud-laden currents again and the whole process was recommenced. Mr. A. C. Seward followed with a clear statement of the botanical evidence bearing on the climatic and other physical conditions under which coal was formed; and Mr. J. E. Marr continued with a general outline of the geological evidence, laying stress on the peculiar coincidence during the Carboniferous period of a dominant vegetation of giant cryptogams with extensive plains of sedimentation and suitable climatic conditions. The debate thus initiated was then thrown open to the meeting and was carried on briskly by numerous speakers, among whom were Dr. Horace Brown, who gave the result of his experiments on the growth of plants in an atmosphere containing a slight excess of carbonic acid gas, and showed a series of lantern slides illustrating these experiments; Prof. P. F. Kendall, who supported the growth-in-place theory for most coals except cannel-coal; Mr. R. D. Oldham, who referred to the absence of seat-earths or under-clays to the seams in the Indian coal-fields; Dr. D. H. Scott, Dr. H. Woodward, Dr. H. O. Forbes, Dr. Wheelton Hind, Dr. Le Neve Foster, Mr. W. Cash, and others. In winding up this somewhat discursive debate, which had occupied the whole of the morning, the president leant strongly towards the growth-in-place theory, and this view was evidently also in favour with the greater portion of the audience.

Dr. E. D. Wellburn next gave two papers on the fossil fish of the Yorkshire Coal-field and of the Millstone Grits. Mr. J. J. H. Teall, President of the Geological Society, then described the plutonic complex of Cnoc-na-Sroine (Sutherlandshire), and discussed the three possible ways in which it may have originated, viz. by (1) successive intrusions; (2) differentiation *in situ*; or (3) modification of the original magma by the absorption of adjacent basic rocks, the conclusion being that the first method has not in this case played an important part, and that the second, coupled perhaps to some extent with the third, has been the main agent in forming the complex. Prof. K. Busz, of Münster, followed with a paper on a granophyre dyke intrusive in gabbro at Ardnamurchan (Scotland), in which it was shown that the granophyre in question has absorbed a considerable quantity of basic material from the previously consolidated gabbro, and has thereby added hornblende and mica to its proper constituents. Both papers provoked lively discussion.

Tuesday was essentially the glacialists' day and they made vigorous use of it, occupying nearly the whole session. Time was found, however, at the opening for a paper by Miss Igerna B. J. Sollas, "On *Naiadites* from the Upper Rhætic of Redland, Bristol"; and there was another break at the close, when Prof. A. P. Coleman, of Toronto, gave an account of the recent discovery of a ferriferous horizon in the Huronian north of Lake Superior, where a band of iron-bearing sandstone and jasper has already been traced for sixty miles in the Michipicoton district, and promises to be of great value from both the economic and the scientific standpoints, as it furnishes an easily-recognised horizon, probably equivalent to that containing the most famous iron mines of the United States, and affords an excellent clue to the stratigraphy.

Of the glacial papers, the first, by Mr. F. W. Harmer, was a theoretical discussion of the influence of winds upon climate during past epochs, in which it was sought to restore hypothetically the distribution of cyclonic and anti-cyclonic areas during the Pleistocene period, and to explain in this manner the phenomena of interglacial periods, which the author believes to have occurred alternately in the eastern and western continents, the conditions of comparative warmth and cold during this period having been local and due directly to meteorological causes. Then followed a series of excellent papers on the glacial phenomena of the West Riding, by Dr. Monckman, Mr. E. Wilson, and Messrs. A. Jowett and H. B. Muff, in which particular attention was drawn to the former existence of glacially-dammed lakes in the side valleys draining to the Aire, and to the overflow channels cut by the streams which had their source in these lakes. The glaciation of the East Riding was afterwards dealt with in two papers by Mr. J. W. Stather; and Mr. R. H. Tiddeman brought forward evidence proving that the raised beach of Gower in South Wales, with the bone-beds which rest upon it in the caves, must be either of pre- or inter-Glacial age, since they are overlain by glacial drift; this matter is of much consequence in the correlation of Pleistocene deposits of the unglaciated parts of our island with those of the glaciated tracts.

At the final meeting on Wednesday morning, Mr. R. D. Oldham discussed the mode of formation of the Basal Carboniferous Conglomerate of Ullswater in the light of his Indian experience, and suggested that it was a torrential deposit formed on dry land near the foot of a range of hills, in a generally dry and hot climate varied by seasonal or periodical bursts of rain. In a second paper Mr. Oldham called attention to good examples of new beach-formation on the shores of Thirlmere Reservoir, and recommended that a photographic survey should be made from time to time to record the progress and growth of this beach. Mr. W. H. Crofts followed with a careful and well-illustrated account of sections in Glacial and post-Glacial deposits in a new dock at Hull; and Mr. A. C. Seward gave a summarised description of the Jurassic flora of the Yorkshire coast, with many fine lantern illustrations. Mr. G. W. Lamplugh afterwards reviewed the evidence as to the age of the English Wealden series, and supported the long-accepted but recently questioned view that the whole of the time-interval between the closing stages of the Jurassic and the commencement of the Aptian is represented.

The reports of committees of research read during the meeting included, among others, Prof. W. W. Watts', on the collection and preservation of geological photographs; Prof. P. F. Kendall's, on erratic blocks of the British Isles; Dr. Wheelton Hind's, on life-zones in British Carboniferous rocks; and Prof. A. P. Coleman's, on the Pleistocene beds of Canada.

The short afternoon excursions were under the leadership of Mr. J. E. Wilson, Mr. H. B. Muff and Dr. Monckman, who were thus able to show in the field some of the phenomena which they had described in their papers. These excursions were well attended and much appreciated by the visitors from a distance, who in this way were enabled rapidly and pleasantly to gain a grasp of the leading features of the local geology.

A well-arranged temporary museum, under the supervision of Mr. J. E. Wilson, for the exhibition of specimens illustrating the papers and the coal-discussion, was located in a large room adjoining the section room, and was especially serviceable in enabling those interested in the particular subjects illustrated to examine the material at their leisure and to compare notes upon it with the exhibitors. The lantern, so often a source of annoyance at the sectional meetings, was ably managed throughout; and indeed the whole of the local arrangements for the accommodation of the section were admirably planned and carried out, the only drawback being that the noise of heavy traffic on the stone pavement outside was at times troublesome.

To sum up the week's work, it may be remarked that there was an unusual number of papers dealing with subjects of broad general interest and therefore well suited for public discussion, and a scarcity of those detailed studies in stratigraphy or classification which, though probably of more permanent scientific value, are ill-adapted for presentation at these meetings; the local papers also were numerous and well above the average in character; petrology and palæontology were both adequately represented; but systematic geology received little attention.

The morning meetings were well attended throughout, but, as usual, in the afternoons only the devoted nucleus of the section remained.

## *ZOOLOGY (AND PHYSIOLOGY) AT THE BRITISH ASSOCIATION.*

THE opening day (Thursday) was devoted to the president's address in the morning and the reports of various committees in the afternoon. The reports were as follows:—

(1) Bird migration in Great Britain and Ireland.—Mr. Eagle Clarke has completed the extraction of the voluminous records of occurrences of birds in Great Britain and Ireland from the periodical literature of 1880-1887. The information thus provided supplements in a most useful manner the original Lighthouse data, and renders it possible for the first time to write an authoritative history of the migrations of each British bird. Mr. Clarke begins the series with a summary of details of the various migratory movements of (i) the Song-Thrush (*Turdus musicus*) and (ii) the White Wagtail (*Motacilla alba*).

(2) Investigations at the Naples Zoological Station.—The utility of the British Association's table was again demonstrated by the number of naturalists who had occupied it during the year. Reports on work done there were submitted by Mr. H. M. Kyle (anatomy of flat-fishes), Mr. E. S. Goodrich (structure of certain polychæte worms), Prof. W. A. Herdman (Compound Ascidians), Mr. R. T. Günther (anatomy of *Phyllirhoë* and certain Cœlenterates), Dr. A. H. R. Buller (fertilisation process

in Echinoidea) and Prof. Ramsay Wright (methods of preservation of specimens).

(3) Investigations at the Plymouth Marine Laboratory.—The British Association table was occupied by Mr. A. D. Darbishire, who investigated the natural history of *Pinnotheres* and the myology of *Calanus*; and by Mr. W. M. Aders, who studied the spermatogenesis of Cœlenterates.

(4) Index Animalium.—Mr. C. Davies Sherborne has made great progress in this important work, and the first part of his catalogue of post-Linnæan names up to the year 1800 is now ready for printing.

(5) Plankton of the English Channel.—Mr. Garstang has completed the five quarterly surveys provided for, and a final report will be presented at the Glasgow meeting.

(6) Zoology of the Sandwich Islands.—Mr. R. C. L. Perkins is again at work in the islands, and reports that already the forests are being extensively destroyed and replaced by sugar cane. It is fortunate for science that the committee foresaw this event, and were enabled to begin their investigations before it was too late. Four parts of the second volume of the "Fauna Hawaiiensis" have been published during the year.

On Friday, Prof. W. B. Scott, of Princeton University, U.S.A., gave an account of the Miocene fauna of Patagonia, based on an elaborate investigation of the Santa Cruz beds. The fauna was characterised by the abundance and variety of Marsupials of Australian type, of Edentates (ground-sloths, glyptodons, and armadillos), of porcupine-like Rodents and primitive Ungulates. There was no trace of tree-sloths and anteaters, of rats, mice, squirrels, hares and rabbits, or of carnivorous Eutheria. The place of the latter was taken by flesh-eating Marsupials, as in Australia to-day. South America was usually regarded as having no Insectivora, but some of the small mammals examined by him appeared to belong to this class. Among the hoofed animals one series was of particular interest in showing the complete evolution of a one-toed type from three-toed ancestors. This monodactyle positively "outhorsed the horse," for even the splints had gone. Yet morphologically it was no horse. It furnished the most conclusive instance he knew of convergent evolution in widely separated groups of animals. In conclusion, Dr. Scott showed that, after the removal of the Miocene barrier, the true carnivora of the modern fauna, together with the llama, deer, tapir, peccary, and the hares and rats, immigrated from North America, while the giant sloths and glyptodons extended their range to the northward.

Dr. Gregg Wilson exhibited a number of eggs and embryos of *Ornithorhynchus*, and described the water-side burrows and nests made by this lowly mammal. The duckmole protects its eggs and nest by blocking the passages between the nest and the entrances with solid walls of earth.

Prof. W. C. McIntosh communicated (through the secretary) a paper on some points in the life-history of the littoral fishes, in which he discussed the mortality of certain shore fishes at different stages of growth.

Major Ronald Ross then delivered a formal lecture on malaria and mosquitoes, dealing more particularly with the life-history of the sporozoan whose reproduction in the blood is the cause of malarial fever, and with the part played by the mosquito *Anopheles* in transferring the parasite by means of its so-called "salivary" secretion to the blood of fresh human hosts. Native children were the chief source of infection, since their blood swarmed with the parasites. The prevalence of malaria, however, might be reduced by efficient surface-drainage, which would check the multiplication of mosquitoes by destroying the pools and ditches in which their larvæ were developed.

In the afternoon Prof. S. J. Hickson exhibited microscopic preparations of *Dendrocometes*, demonstrating the existence of micronuclei in this suctorian, and the remarkable fusion of the macronuclei during conjugation. He advocated the employment of brazilin with iron-alum as a convenient substitute for the iron hæmatoxylin method of staining.

Dr. J. F. Gemmill described the anatomy of the head in cyclopean trout embryos. The cerebral lobes are more or less united, and the *trabeculae cranii* are fused together anteriorly, and bent down below the median eye or eyes. The infundibulum and pituitary body are entirely absent; the optic nerves are rudimentary or absent, and the eyes, though provided with retina and choroid, have no choroidal fissure. In some specimens the mouth opening is absent, and the lower jaw arch greatly shortened.

Prof. R. Burckhardt of Basel communicated two papers on some causes of brain-configuration in selachians, and on the systematic value of the brain in selachians. He showed the profound influence of the position of the eyes and other superficial organs upon the shape of the brain, and advocated the employment of cerebral characters in the classification of cartilaginous fishes.

On Saturday, the papers were of a more or less physiological character, as follows:—

Prof. Marcus Hartog: "On a peptic zymase in young embryos," in which the author announced the confirmation of his discovery in 1896 of a peptic zymase in young embryos of the frog, in the entire embryo of the chick after twenty-four hours, and in the extra-vascular blastoderm of the three days' chick. He concluded that the law holds good for animals, as well as plants, that the cell cannot directly utilise the reserves it contains, but only the products of their hydrolysis, and this hydrolysis is not a function of the living protoplasm, but of the zymases it forms. These facts also explain apparent exceptions to Herbert Spencer's law of division at the doubling of the volume. A cell that is only accumulating reserve material has no need to constantly readjust its surface to its volume. When, however, the formation of a zymase enables it to utilise its reserves, and its protoplasm grows at the expense of the products of their digestion, the need for augmented surface declares itself, and we get the repeated cell divisions so marked in the "segmentation" of the embryo.

Dr. R. Irvine: "On the mechanical and chemical changes which take place during the incubation of eggs." Hen's eggs during incubation lose weight daily, principally through the oxidation of their carbon and hydrogen, parts of which pass off as $CO_2$ and $H_2O$ through the shell. The percentage of ash is increased by absorption of lime from the shell.

Prof. Gotch described some recent experiments on the physiological effect of local injury in nerve which led to the important conclusion that an electrical disturbance was not always a concomitant of the passage of a nervous impulse.

In addition to the above, Prof. Johnson Symington read papers on the articulations between occipital bone and atlas and axis in the mammalia, and observations on the development of the cetacean flipper, and exhibited a convenient hand-magnifier for demonstrating slide-preparations to lecture-classes (Erbe, Tübingen).

The reports of committees on the following subjects were also communicated:—(1) The physiological effects of peptone when introduced into the circulation (Prof. W. H. Thompson). (2) Comparative histology of the suprarenal capsules (Mr. Swale Vincent). (3) The vascular supply of secreting glands (Dr. J. L. Bunch). (4) Electrical changes in mammalian nerve (Dr. J. S. MacDonald), and (5) The comparative histology of cerebral cortex (Dr. G. Mann).

On Monday, Mr. R. T. Günther read a note on *Mnestra parasites*, Krohn, in which he submitted reasons for referring this parasitic medusa to the family Cladonemidæ (Anthomedusæ), owing to its possession of compound tentacles with clavate appendages and other cladonemid characters.

Prof. L. C. Miall reviewed the respiratory organs of aquatic insects. He contrasted the slight nature of the adaptations to aquatic life which are exhibited by adult insects with the remarkable modifications for the same end which occur in insect larvæ. He explained the difference as probably due to the fact that profound structural changes in adult insects would interfere with their powers of flight, which were of importance for mating and other purposes. Among larvæ there were two principal lines of modification, (1) specialisation of the spiracular apparatus by which air could be inspired directly from the atmosphere through the surface film of water, and (2) development of a closed tracheal system, by which air was extracted from its solution in the surrounding water. This latter series culminated in a purely vesicular system, destitute of tracheæ, and finding its nearest parallel in the air-bladder apparatus of physoclist fishes.

Mr. T. H. Taylor described the tracheal gills of *Simulium*, whose mode of respiration presented peculiar difficulties still unsolved.

Mr. J. J. Wilkinson described the pharynx of *Eristalis*, and Mr. N. Walker the structure and life-history of the gooseberry sawfly.

In the afternoon Mr. Stanley Gardiner opened with the interim report of the committee appointed to investigate the structure, formation and growth of the coral reefs of the Indian Ocean. Special attention was given to the island of Minikoi, in the Laccadive group. It was clear from their observations that in this atoll there had been an elevation of the original reefs to a height of at least 25 feet above low tide level. All their evidence showed that the lagoons of atolls were generally formed by the solution of the central rock of originally more or less flat reefs.

Prof. R. Burckhardt followed with a paper on the anatomy and systematic position of the Læmargidæ. He recorded the discovery of luminous organs in nine species of Læmargidæ and Spinacidæ. The affinity of these families of sharks was further evidenced by his discovery of a cartilage hook in the dorsal fins of *Laemargus*.

Prof. Burckhardt also showed photographs and other illustrations of the nestling kagu (*Rhinochetus*), a rare flightless bird of New Caledonia.

Prof. R. J. Anderson described the dentition of the seal; and Mr. Graham Kerr, on behalf of Mr. G. E. H. Barrett-Hamilton, exhibited some skulls of Antarctic seals (chiefly Phocidæ) brought home by the Belgian expedition.

On Tuesday, Mr. N. Annandale exhibited a number of photographic slides illustrating the appearance and habits of some Malay insects under natural conditions. One striking series represented the pupa of a Mantis (*Hymenopus bicornis*) seated on an inflorescence of the so-called "Straits Rhododendron" (*Melastoma polyanthum*), a detailed resemblance to which is brought about by the colour and shape of the insect, and by the extraordinary attitude which it adopts upon the flower.

Prof. E. B. Poulton also showed a large number of slides, representing the collections of insects made by Mr. G. A. K. Marshall in Mashonaland and Mr. R. Shelford in Borneo, as arranged in the Oxford Museum to illustrate the general principles of Müllerian mimicry. An interesting series of mutilated butterflies caught at large showed the comparative rarity of indiscriminate injuries by birds, and the frequency with which enemies aimed at the conspicuously marked tips of the fore-wings and at the back of the hind-wings, where tail-like processes were so commonly developed, these being just the places where the bites would be least dangerous to the insects.

Other slides, illustrating mimicry and protective resemblance, were exhibited by Mr. Mark L. Sykes; and Prof. Lloyd Morgan described some recent experiments upon newly-hatched chicks, which showed that the avoidance of distasteful forms by birds is not instinctive, but the fruit of experience. Chicks fed for a time on palatable food placed on black-and-orange banded slips of glass did not hesitate to attack the distasteful caterpillars of the cinnabar moth when these were eventually offered them; whereas chicks which had been accustomed to associate the same coloured slips with bad food refused to attack the similarly striped caterpillars. These observations provided a sound experimental basis for the Müllerian theory of mimicry.

Mr. F. W. Gamble described the results of investigations made by Mr. F. W. Keeble and himself on the colour changes of various prawns, especially *Hippolyte varians*, his paper being illustrated by a series of living specimens as well as by lantern slides. The prawns adapted their colours to those of surrounding weeds; but, whatever their colour during the day, they always assumed a characteristic blue colour at night. This change, in newly-caught specimens, came on at the proper time quite independently of the darkness, and the morning phase would be resumed at daybreak, even when the animal was kept in the dark. After a few days under such unnatural conditions, however, the periodicity became altered.

A paper, by Dr. Æneas Munro, on the locust plague and its suppression concluded the business of the section.

---

## GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE work in Section E at the Bradford meeting was somewhat limited in amount, but its quality was in no way below the average. In fact, the number of "popular" papers was smaller than usual, while those of a more serious character predominated. The section was excellently housed in the Church Institute, and the meeting began with a presidential address of quite a novel character. Sir George Robertson took the British Empire as his text, and laid great stress on the relative shrinkage of distances by the improvement of means of communication by land and sea, a fact which in great measure neutralised such ill effects as might arise from continuous expansion of territory.

The keynote struck by the president was geography as the science of distances, and in unison with it a series of papers dealt with problems of which distances and means of transport were the essential features. Mr. E. G. Ravenstein discussed the question of foreign and colonial surveys in a comprehensive paper, in which he pointed out the manner and extent of the official surveys of the chief countries of the world. While recognising that the British Ordnance Survey fell short of perfection, he considered that its accuracy was not equalled by the maps of any other country. He strongly urged the adoption of a more systematic method of surveying in Africa, in many parts of which the only existing maps were produced by travellers with inadequate assistance and many other things to do. In commenting on the paper, Colonel Johnston, the Director-General of the Ordnance Survey, explained the position of South Africa with regard to its surveys. He said that a nearly perfect system of triangulation had been carried out, but this has not yet been utilised by being made the foundation of a detailed survey.

Mr. B. V. Darbishire read a paper on military maps, with special reference to the use of the Ordnance Survey Maps in field manœuvres.

Colonel Sir Thomas H. Holdich discussed the question of a railway connection between Europe and India. He considered the northern approaches to India across Kashmir or the Hindu Kush from the Oxus valley to be impracticable. On the other hand there appeared to be no insurmountable difficulty in the way of a connection by the Hari-rud valley, through which approach a distance of only 500 miles intervened between the farthest outposts of the existing railways, Kushk on the Russian side and New Chaman on the Indian. The new line would pass by Kandahar. This line could, in the opinion of the author, be made to pay by local traffic, and he believed it would strengthen rather than weaken the defences of India.

Mr. C. Raymond Beazley read a paper, which was largely historical and statistical, on the Trans-Siberian railway.

Mr. G. G. Chisholm gave a very timely forecast of the probable economic changes which may be expected to result from the imminent development of the resources of China by modern methods. These would include, in his opinion:—A rise in prices in China, especially in the industrial regions; a demand for food-stuffs not likely to be supplied by China itself; a great stimulus to the food-producing regions most favourably situated for meeting this demand, more particularly Manchuria, Siberia, and western North America; and the creation of a tendency to a gradual but prolonged rise in wheat and other grain prices all the world over, reversing the process that has been going on since about 1870.

Mr. Edward Heawood treated of the commercial resources of tropical Africa, and his paper also partook of the spirit of forecast, his expectations being that Africa will greatly increase in importance by the cultivation of tropical plantations.

The travel papers which excited the most interest were those contributed by Mr. Borchgrevink on his expedition to the Antarctic regions and by Captain H. H. P. Deasy on his journeys in Central Asia. Both were illustrated by remarkably fine lantern slides. As the facts which they recounted have already been published, it is unnecessary to summarise them here.

Physical geography occupied a large part of the time of the section, and, with regard to this part of the work, it is impossible to refrain from expressing the desire that some arrangement might be come to with regard to the section in which papers lying on the borderland between different subjects should be treated. With regard to meteorology, for instance, might it not be arranged to read all climatological papers—the essential principle of which is geographical distribution—at Section E, and only the theoretical papers or those dealing with instruments and atmospheric physics at Section A?

On this occasion the report of the committee on the climate of tropical Africa, of which Mr. H. N. Dickson is secretary, was read to Section E, and a remarkable discussion of the geographical distributions of relative humidity was presented by Mr. E. G. Ravenstein to the same section. In this he said that, notwithstanding the paucity of available material, he had ventured, in 1894, to publish in Philip's "Systematic Atlas," a small chart of the world showing the distribution of humidity, and he now placed the results before this meeting with some diffidence. His charts brought out the broad features of the subject, and to reduce the sources of error he had limited himself to indicating four grades of mean annual humidity, the upper limits of which were respectively 50 per cent. (very dry), 65 per cent., 80 per cent., and 100 per cent., (very damp). The relative humidity over the oceans might exceed 80 per cent., but in certain regions ("horse latitudes") it was certainly much less, and in a portion of the Southern Pacific it seemed not to exceed 65 per cent. One chart exhibited the Annual Range of Humidity, viz. the difference between the driest and the dampest months of the year. In Britain, as in many other parts of the world, where the moderating influence of the ocean was allowed free scope, this difference did not exceed 16 per cent., but in the interior of the continents it occasionally exceeded 45 per cent., spring or summer being exceedingly dry, whilst the winter was excessively damp, as at Yarkand, where a humidity of 30 per cent. in May contrasted strikingly with a humidity of 84 per cent. in December. This great range directed attention to the influence of temperature (and of altitude) upon the amount of relative humidity, for during temperate weather we were able to bear a great humidity with equanimity, whilst the same degree of humidity, accompanied by great heat, may prove disastrous to men and beasts. Hence, combining humidity and temperature, the author suggested mapping out the Earth according to sixteen *hygrothermal types*, as follows:—(1) Hot (temperature 73° and over) and very damp (humidity 81 per cent. or more): Batavia, Camaroons, Mombasa. (2) Hot and moderately damp (66–80 per cent.): Havana, Calcutta. (3) Hot and dry (51–65 per cent.): Bagdad, Lahore, Khartum. (4) Hot and very dry (50 per cent. or less): Disa, Wadi Halfa, Kuka. (5) Warm (temperature 58° to 72°) and very damp: Walvisch Bay, Arica. (6) Warm and moderately damp: Lisbon, Rome, Damascus, Tokyo, New Orleans. (7) Warm and dry: Cairo, Algiers, Kimberley. (8) Warm and very dry: Mexico, Teheran. (9) Cool (temperature 33° to 57°) and very damp: Greenwich, Cochabambo. (10) Cool and moderately damp: Vienna, Melbourne, Toronto, Chicago. (11) Cool and dry: Tashkent, Simla, Cheyenne. (12) Cool and very dry: Yarkand, Denver. (13) Cold (temperature 32° or less) and very damp: Ben Nevis, Sagastyr, Godthaab. (14) Cold and moderately damp: Tomsk, Pike's Peak, Polaris House. (15) Cold and dry. (16) Cold and very dry: Pamirs.

The actual mean temperature of the Earth amounted, according to his computation, to 57° F., and this isotherm, which separated types 8 and 9, also divided De Candolle's "Mikrothermes" from the plants requiring a greater amount of warmth.

Mr. Vaughan Cornish described his recent observations on snow ripples with beautiful photographic illustrations, and Prof. J. Milne gave an account of the large earthquakes recorded in 1899. Mr. R. T. Günther described the peculiar character of the coast of the Phlegræan Fields near Naples, and showed that by observations of the numerous submerged buildings of that district it might be possible to determine the date and duration of the fluctuations of the land and sea level during the last twenty centuries. The Association subsequently voted a money grant to assist him in carrying out the researches which he had suggested.

Dr. H. R. Mill exhibited and described the new insulating water-bottle designed by Profs. Pettersson and Nansen, and made by Messrs. Ericsson, for obtaining water-samples from any desired depth and bringing them up without change of temperature. The new apparatus was tested by Prof. Nansen last August on board the *Michael Sars* in the North Atlantic, and found to be completely satisfactory.

Dr. Mill also read a paper on the treatment of regional geography, in which he laid down the general principle that the fixed conditions of the land surface had first to be described, and then the mobile distributions, which were modified by the fixed forms. As an example, he dwelt at some length on the configuration of a section of the South Downs and the effect of this configuration in determining the distribution of rainfall in the district, a problem which he hoped to treat in greater detail at a future date.

Mr. J. E. Marr described the typical land form known as a moel, with special reference to the forms it assumed when dissected by sub-aërial erosion.

Two educational papers of much interest were read. One by Mr. T. G. Rooper dealt with the progress made in teaching of geography in the elementary schools of the West Riding since 1883. He illustrated it by the exhibition of a series of remarkable relief models on different scales produced by school teachers and used by them in their regular work. Some of these were of typical features, such as the Red Tarn, to typify a mountain lake, others of the actual school district taken from the Ordnance map, and others, on a small scale, of large parts of the country. The second paper was by Mr. E. R. Wethey, who gave a demonstration of his method of teaching commercial geography by the use of lantern maps, diagrams and pictures, a large number of which, in novel and striking forms, he showed upon the screen.

Educational questions have always occupied a considerable share of the time of Section E, and the committee very cordially supported the proposal to recommend the Council of the Association to form a new Section for the discussion of education in a more complete and technical manner than could be secured in a gathering of votaries of one isolated branch of science.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

OXFORD.—Mr. E. S. Goodrich has been elected to a fellowship in natural science at Merton College.

CAMBRIDGE.—In his annual address to the Senate at the opening of the term, the Vice-Chancellor announced that the Benefactor Fund amounted to 55,000*l.*, and that the Squire Trustees had agreed to contribute 15,000*l.* towards the erection of the Law School. The plans for the Botanical and Medical Departments have been approved, and building will shortly commence; but fresh benefactions are still needed to meet the urgent demands for further accommodation.

The new Department of Agriculture, under the able guidance of Prof. Somerville, is now well started. The funds at its disposal have enabled it to secure an efficient staff, and it is provided with an excellent experimental farm. The University has sought to encourage the study by establishing a special amination in agricultural science for the B.A. degree.

Dr. L. Humphry has been appointed assessor to the Regius Professor of Physic; Sir G. G. Stokes and Prof. Darwin electors to the Isaac Newton Studentship in Physical Astronomy; and Dr. Tatham an examiner for the diploma in Public Health. Mr. Leathem (St. John's) and Mr. Grace (Peterhouse) have been appointed moderators, and Mr. Whitehead (Trinity) an examiner, for the Mathematical Tripos.

Rooms for work in clinical pathology, bacteriology, &c., have just been erected by the staff and presented as a gift to Addenbrooke's Hospital. They will be open for work, under the direction of Prof. Sims Woodhead, during the present term.

At Emmanuel College a research studentship of 100*l.* has been awarded to Mr. J. Mellanby. Grants have been made from the studentship fund of 60*l.* to Mr. G. F. Abbott, and of 40*l.* to Mr. D. G. Hall. At Queen's College the Rev. C. H. W. Johns has been elected to the office of lecturer in Assyriology.

---

MR. C. R. P. ANDREWS, of St. John's Training College, Battersea, has been appointed first principal of the new Government training college to be opened at Perth, Western Australia.

DR. SAMSON GEMMELL, of Anderson's College, Glasgow, has been appointed professor of clinical medicine in the University of Glasgow, in succession to Prof. McCall Anderson.

DR. CULLIS, professor of mathematics at the Hartley College, Southampton, has been appointed professor of mathematics at the Presidency College, Calcutta.

MR. J. F. HUDSON, late lecturer in mathematics at Jesus College, Oxford, has been appointed professor of mathematics at the Hartley College, Southampton.

MR. J. STUART THOMSON, formerly demonstrator of zoology at the School of Medicine of the Royal Colleges, Edinburgh, has been appointed lecturer in botany and zoology at the Municipal Science, Art and Technical Schools, Plymouth.

THE School of Engineering of Columbia University, New York, announces a new course of study dealing with the construction of automobiles, self-propelling road engines and railway cars.

PROF. GOSS has been made dean of the Engineering Schools of Purdue University, Lafayette, Ind., and Prof. L. C. Glen, of South Carolina College, has been appointed to the chair of geology in Vanderbilt University.

MR. PERCY H. FOULKES has been elected first principal of the Harper Adams College, Newport, Salop. He will enter upon his duties on January 1, 1901, soon after which date the college will, it is expected, be ready to receive pupils.

At a general meeting of Convocation of the University of London, held on Tuesday last, the following were elected to serve as members of the Senate under Section 12 of the statute of the reconstructed University:—Mr. John Fletcher Moulton, Dr. J. D. McClure, Sir A. Kaye Rollit, Dr. T. B. Napier, Dr. J. B. Benson, Dr. T. L. Mears, Sir H. H. Cozens-Hardy, Dr. T. Barlow, Mr. J. F. Payne, Sir Philip Magnus, Dr. S. Bryant, Dr. C. W. Kimmins, Dr. F. Clowes, Prof. Silvanus Thompson, Dr. F. S. Macaulay, and Mr. J. W. Sidebotham.

During the past week very many addresses have been delivered to students at the opening of the winter sessions of the various science, technical and medical schools in London and the provinces, in the course of which much excellent advice has been given. An article dealing with some of the utterances made to medical students is to be found in another part of the present issue. In this column we refer, and only very briefly, to two addresses given to students of other branches of knowledge, viz. those by Sir Alexander Binnie at the opening of the Central Technical College, on October 2, and by Prof. Le Neve Foster at the distribution of medals, prizes, &c., to the students of the Royal College of Science, on October 4. The subjects chosen for their addresses by both speakers were well suited to the occasion, and should prove of much service to the audiences who listened to them. Prof. Foster took as his topic "Common Sense," in the course of which he referred to the remark of Prof. Huxley that science was organised common sense, and the two or three years' training in science which students received at the college was, therefore, simply training in ordinary common sense. If they wished to succeed in any calling they must exercise the faculty of thought. It was difficult to realise that times were changing, but change was everywhere taking place, and they must throw aside the idea that in the production of British manufactures the methods that had come down to them from their forefathers were necessarily the best. In Lancashire it was said that what Lancashire did to-day Great Britain would do to-morrow. They might say that what the scientific man did to-day the manufacturing man would do to-morrow. The laboratory experiment of to-day was, in fact, the manufacturing process of to-morrow. But if the student desired to take an active part in the improvement of the industrial life of the country and of manufacturing processes, he must work hard and not place too much reliance on his teacher. All that the professor could do was to give the student a general ground-work upon which afterwards by his own experiments he could build up his frame-work of knowledge. Sir A. Binnie in his address contrasted the advantages which students of to-day have over those educated in the middle of the present century, and urged upon his hearers not to confine themselves merely to the curriculum of study laid before them, or to take too narrow a view or devote themselves exclusively to one particular branch of learning. The aim of the speaker was to impress upon his audience that to be a true student of science the mind must be opened out and widely cultivated by observation to grasp every detail, as it often occurs that it is among the almost unnoticed minutiæ of a particular science that those wonderful correlations that lead in the future to wide results are to be found. He spoke of the necessity of acquiring a wide and broad view of the subjects which should engage the student's attention for the reason that he felt that education could only be complete when studied as a whole, and the beauty of all the different sciences brought clearly before the mind. Further, one can never tell, when entering upon active work, into what avenues or by-paths of practice he may be led, and to illustrate this Sir A. Binnie referred to his own experience. He also urged upon his hearers to study the history of their profession, and of the various discoveries which have been made in the different branches of science to which they would apply themselves. Altogether the students are to be congratulated upon the helpful advice tendered to them.

## *SOCIETIES AND ACADEMIES.*

### Paris.

**Academy of Sciences,** October 1.—M. Maurice Lévy in the chair.—On the absorption of free oxygen by normal urine, by M. Berthelot. Normal urine absorbs free oxygen in amounts larger than those corresponding to the solubility of oxygen in water. The acidity is not altered by the absorption.—Remarks on the acidity of urine, by M. Berthelot.—On the distribution of the horizontal component of the earth's magnetism in France, by M. E. Mathias. As the result of work spread over a period of six years in the neighbourhood of Toulouse, it was found that a very simple formula would combine the results of all the observations, namely: $\Delta H = -1{\cdot}26\ (\Delta \text{ long.}) - 7{\cdot}42\ (\Delta \text{ lat.})$, in which $\Delta H$ was the difference between the measurement for an element at a place X and that of the corresponding element at Toulouse. It was further found that the above formula applies to the whole of France.—On the selenides of nickel, by M. Fonzes-Diacon. Nickel leaflets heated in a current of nitrogen carrying small quantities of selenium vapour give cubical crystals of a selenide of the composition NiSe. Another selenide approximating in composition to $Ni_3S_4$ is obtained by heating anhydrous nickel chloride in a current of hydrogen selenide at a dull red heat. At 300° C. the diselenide $NiS_2$ is obtained as a greyish-black, friable mass. All these products heated to a white heat in a current of hydrogen give a sub-selenide, $Ni_2Se$.—Oxycelluloses from cotton, flax and hemp, by M. Leo Vignon. Purified fibres of various textile material were submitted to the oxidising action of hydrochloric acid and potassium chlorate; the yield in all cases was the same, about 70 per cent.; phenylhydrazine furnished the same osazone. Small differences were observed in the reducing powers of the oxycelluloses from different sources.—On the mutability of *Œnothera Lamarckiana*, by M. Hugo de Vries. This furnishes an example of the rare phenomenon of a state of mutability in a pure species. The new species appears suddenly without preliminary or intermediate stages; the transformed individual shows all the characters of a new type, although the parents and grandparents are absolutely normal. The seeds of the transformed individuals give rise to the new type only, no tendency being observed to revert to the characters of *Œ. Lamarckiana*.—On the Eocene of Tunis and Algiers, by M. L. Pervinquière.—The ravine of Chevalleyres and the retrogression of torrents, by M. Stanislas Meunier. Attention is drawn to the mode of formation of this *col*, the size of which would appear out of all proportion to the small stream to which the ravine is undoubtedly due. The transfer of rock masses, and other effects usually ascribed to glacier action, may be traced to this torrent.—Observations of a meteor which fell on the evening of September 24, by M. Jean Mascart. The meteor, the nucleus of which was star-like and very bright, was seen at 10.16 p.m. on September 24 between Meudon and Bellevue.

# A Great Book. A Great Bargain.

# A FIRST PAYMENT OF

# FOLLOWED BY LESS THAN

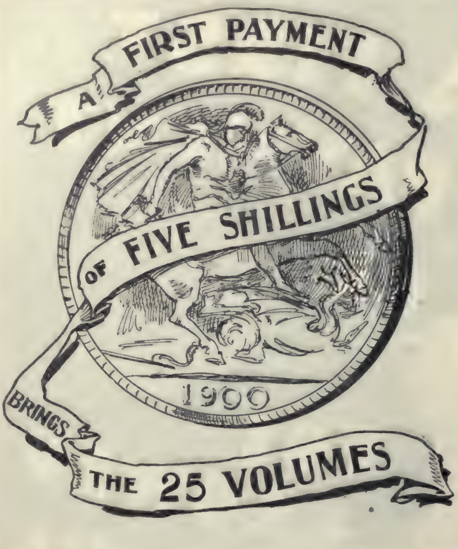
# A DAY

## Do you realise what the Encyclopaedia Britannica is?

No book exists which is at all to be compared with the Encyclopædia Britannica. The editors intended to embrace all knowledge in their Ninth and monumental Edition of the great national library, and indeed the whole of the world is covered in its 22,000 pages and illustrated in its 338 full-page plates, its 671 maps and plans, its more than 9,000 other illustrations. But this generous acceptance of the magnitude, the merely physical magnitude, of their task was not all, was not the best part of their plan for achieving it. The information contained in the work was to be concise and brilliantly handled, as well as full and universal, and it was also to be the best obtainable, the finest fruits of modern scholarship and research, so that the work might be at once a book of reference and a collection of exhaustive and brilliant treatises, so that it might interest and inform the general reader, and at the same time satisfy the specialist in any branch. The editors gained their end in the only way by which it could be reached, by acquiring the services of the highest authorities of the age.

Even those who know the book well, and are accustomed to the brilliance which characterises its articles (they number 16,400), are always freshly astonished when they are reminded of the world-wide celebrity of the 1,100 contributors who made the Encyclopædia Britannica "the Greatest Work in the world." Wherever one looks one finds the work of men whose authority is acknowledged the world over, men who not only have full knowledge of their subjects, but also have themselves furthered by their own original researches the science or the art of which they treat in the Encyclopædia Britannica. Lord Kelvin, Sir Robert Ball, Lord Rayleigh, Sir William Crookes, Sir Archibald Geikie, Sir Norman Lockyer, Professor Dewar, Professor Ray Lankester, Sir Frederick Abel in science, Swinburne, Sir Richard Jebb, Sir George Macfarren, Andrew Lang, Austin Dobson, William Morris, John Morley, Mrs. Humphrey Ward, Sir George Reid, W. E. Henley, George Cable, Matthew Arnold, Robert Louis Stevenson, in music, arts, and letters; such names are not only names for to-day, the words of such writers will always carry with them an authority which no mere expert, however well informed, could claim for his. The work of such contributors is hardly to be measured in terms of money, yet one may admire the far-sighted generosity of the publishers who willingly paid away more than £60,000 for the manuscript alone. And if to this be added the cost of paper, type, illustrations, and binding worthy of such matter, it appears that the Encyclopædia is the most costly book ever offered to the public. And this is the book which you may now have for less than half the regular publishers' price.

[See Next Page.]



## Do you Realise that the Book is a Book for You?

Whatever may be your profession, whatever may be the nature of your interests and the direction of your ambitions, you will find in the Encyclopædia Britannica much to help you at your work, to forward you in your hobby, to encourage you in your ambitions. No man, however wide may be his activities, however quick his understanding, can satisfactorily live off his own personal experience. The Encyclopædia Britannica takes the reader over the whole world, giving him the experience of others who have travelled further afield or whose path in life has fallen in other places. It is a book calculated to appeal to everyone, and since it has been brought within the reach of everyone, it is interesting to remark what a comprehensive list is to be made from those who have purchased "THE TIMES" Reprint. The fifty-two peers include Lord Salisbury; there are 20 bishops, and 80 officers in the Army and Navy, starting with Lord Roberts. Mr. Kipling is among the long list of authors, and the late Lord Russell appears in the roll of judges. Finance and manufacture are represented by some of the biggest names. Such a list shows in what respect the Encyclopædia Britannica is held by the most distinguished men in the country. But there is another list which may be made, a list no less significant, for it shows how the work is rated by those who still have their way to make. There are clergymen who are not yet bishops (sixty out of the first thousand subscribers to the DAILY MAIL offer were clergymen), officers who are not yet generals, lawyers, doctors, engineers, architects, who still have names and a fortune to make. Perhaps you think that these professions account for most of the names upon the registers, but this is not so. Manufacturers, men engaged in business of every sort, accountants, land agents, auctioneers, Government inspectors, make up a total as great as that of the learned professions. The man of business is no less keen to possess a book which may be of practical use to him. The third highest figure in the list belongs to merchants. They are followed by manufacturers and managers in every sort of works, iron foundries, chemical works, cycle manufactories, breweries, lace factories, collieries, boot and shoe factories, cotton mills, laundries. The appeal of the book to practical men, moreover, could hardly be better exemplified than by the number of farmers and market gardeners who are down among the subscribers.

In the last announcement in which we put before readers of *Nature* the unique offer of the great library, we attempted to suggest the grasp, the fulness, the brilliance which characterises the scientific side of the many-sided book. The contributors whose names we mentioned (such names as Lord Kelvin, Sir William Crookes, Professor Newton, Professor Ray Lankester, Sir Robert Ball, Sir Archibald Geikie, Sir Norman Lockyer, Lord Rayleigh, Professor St. George Mivart, Professor Dewar) are much more than experts fully equipped with information, they are men who have not only written the history of their various branches, but also helped to make that history by their own original researches. They are men whose names are not only for to-day. It was on such a noble scheme that the editors prepared the whole of the famous 9th Edition. In every department of knowledge they claimed the services of men who were making history, of original thinkers. There is a very

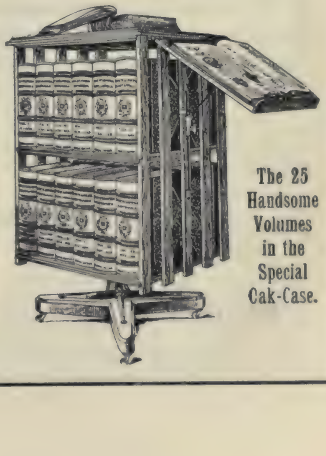
**A Book that can never again be sold on such extraordinary terms.**

## A Book that, if you are to get it while it is to be had so easily, you must secure at once.

real sense in which the Encyclopædia Britannica may be called a "practical book." Very rarely in the history of learning could such a collection of talent be matched. The contributors were men who could speak with the authority of Discoverers, setting forth in every province of knowledge the new spirit of the age. For if in the Encyclopædia Britannica we have the best fruits of the new learning in science, so also we have the new movement in decoration set forth by Marris, the contemporary admiration for Elizabethan drama in the work of Mr. Swinburne, the new founder for the period of the Renaissance presented by no less an authority than John Addington Symonds. All the collected learning of the past is in the pages of the Encyclopædia Britannica, and there also in its fulness is the new knowledge which most men only half know, the new point of view from which we are ready to see things if only we may have authoritative direction. Such direction is to be found on every subject in the Encyclopædia Britannica. For the editors went the way to make not only a work of reference, fit to answer a question, but also a collection of treatises covering the whole world. That no book of reference has ever been put together by such authorities as made the Encyclopædia Britannica "the greatest work in the world" goes without saying. But it is equally true that no man, even if he could gather from the ends of the earth the best text books written on every subject, could make a library at all to be compared with the Encyclopædia Britannica. The charm and usefulness of the Encyclopædia Britannica is that its possessor has not only his own subject brilliantly treated to refer to, but everybody else's subject at his service, and the naturalist may read Sir Richard Jebb upon some classical point with as much confidence as he would turn to the contributions of Professor Cayley if he were a mathematician. It is, in fact, a book calculated to interest everyone, and especially those to whom the scientific method, as it is used by the greatest men, appeals strongly.

## Do you Realise the Bargain Offered You?

The arrangement effected between the Daily Mail and "The Times" in the matter of "The Times" Reprint of the Ninth and latest Edition of the Encyclopædia Britannica, makes it possible to put before the public a bargain unprecedented in the history of book-selling. An invaluable work, a complete library, which everyone desires to possess, is offered at less than half the published price. That is the first point in the remarkable bargain. The second point is this—that the price, the "less than half-price," need not be paid at once; it may be paid in small monthly instalments of 12s. each. But there is a third, and most important, point in the bargain. It is this. Although you need not pay the price all at once, you get all the 25 volumes at once, for they are sent you entire upon receipt of a preliminary payment of 5s. For the sum of 5s., therefore, the 25 volumes of "The Times" Reprint of the Encyclopædia Britannica is put into your hands to use from A to Z. While you and your household are enjoying the possession of the work, you complete your purchase by sending in monthly payments of 12s., and when the purchase is completed you will have paid something less than half the price which the publishers put upon exactly the same book. Is this not a unique thing in book-selling? The novel arrangement places the great national library well within reach; it is no longer an unattainable treasure, it is no longer a work which necessitates a journey to a public library for the man who would consult it. The Encyclopædia Britannica may now be, where such an invaluable treasury of all knowledge should be, at everyone's elbow. And you may have it at your elbow, for constant reference and study, by spending the small sum of 12s. a month, which means saving from your other expenses a little less than 6d. a day.



The 25 Handsome Volumes in the Special Cak-Case.

***An Enquiry Form is given on the next page.***

Specimen Volumes, Bindings and Bookcase can be seen, and full details obtained, at the following places:

## Do You Realise the Need for Haste?

*We want you to realise that what we are telling you is absolutely true, and what we are telling you and have told you before is just this, that if you wish to make sure of not missing this great opportunity that we are giving to you you must make haste, you must send in your order promptly. You will realise at once the need for haste when we tell you that in the first place the present offer can remain open only for a limited time, and only a limited number of sets can be sold on these present terms. Judging from the very large demand that has already been made for sets of the* Encyclopædia Britannica *upon the* DAILY MAIL *terms, the limited space of time will be still further limited by the fact that before the date upon which this offer must be withdrawn has been reached, the limited number of sets will have been taken up. It is not only that after the date upon which this offer must be withdrawn we shall not be able to accept any orders, but that also (and this promises to be long before that time), after we have accepted an order for the last set of which we can dispose, all other orders will be too late. These plain facts will surely make you realise that if you wish to be in time you must make haste. Of course, in every case we should like you to be able to come up to one of the many offices that we have opened where you can see for yourself, handle, and read, the volumes of the* Encyclopædia Britannica, *where you can see the different bindings, where you can see the revolving bookcase, which has been specially manufactured for subscribers and is sold to them at an extremely low price, and where also you can obtain fuller details of the bargain offer now made to you than we can possibly give you in any advertisement. But if you are unable to make it convenient to call you can obtain equally full information by using our Enquiry Form, or by sending us a post card, in both cases the cost being to you only a halfpenny, and you may fully rely upon the information which will be conveyed to you by the illustrated prospectus of the* Encyclopædia Britannica, *this prospectus containing not only an account of the book, but facsimile pages, extracts from numerous articles, and specimens of the coloured plates, maps, and other illustrations. In fact, this illustrated prospectus may very well be termed a "sample book." Every statement in it you may rely upon as being an under, rather than an over statement of the facts. Of this we feel so sure that we know that when you receive your books you will be astonished at three things: you will be astonished that we have been so moderate in what we have said about them, you will be astonished at finding them an even more valuable and handsome possession than even you expected them to be, and, above all, you will be amazed that you have been able to acquire this book, not only at such an extraordinary bargain price, but upon an equally extraordinary and convenient system of payment.*

### ENQUIRY FORM.

**To be sent to the "DAILY MAIL" OFFICE.**

***This Enquiry Form can be sent in an open Envelope with only a Halfpenny stamp***

*Please send me the Illustrated Prospectus of the "Encyclopædia Britannica," order form, and full details of the "Daily Mail" offer, and provisionally reserve me a set of the Volumes.*

THURSDAY, OCTOBER 18, 1900.

## *THE SUBORDINATION OF THE INDIVIDUAL TO THE WELFARE OF THE SPECIES.*

*The Foundations of Zoology*. By William Keith Brooks, Ph.D., LL.D., Professor of Zoology in the Johns Hopkins University. Pp. viii + 339. (Columbia University Press. New York: The Macmillan Co. London: Macmillan and Co., Ltd., 1899.)

THIS volume forms the fifth of the Columbia University Biological Series edited by Prof. H. F. Osborn and Prof. E. B. Wilson, and it is appropriately placed beside the well-known earlier memoirs which deal with historic, phylogenetic and ontogenetic evolution. The traditions of the series are sufficient warrant for the admirable editing, printing and general appearance of the volume.

The author arranges his work in fourteen chapters corresponding to thirteen lectures, the sixth being divided into two parts. The subjects which follow the introductory lecture are "Huxley, and the Problem of the Naturalist," "Nature and Nurture," "Lamarck," "Migration in its Bearing on Lamarckism," forming the titles of the second, third, fourth and fifth lectures. The sixth deals with "Zoology and the Philosophy of Evolution," and its second part with the views of Galton and Weismann. "Galton, and the Statistical Study of Inheritance" is the subject of the seventh, and "Darwin and the Origin of Species" that of the eighth lecture, the subjects of the remaining lectures being "Natural Selection and the Antiquity of Life," "Natural Selection and Natural Theology," "Paley, and the Argument from Contrivance," "The Mechanism of Nature" and "Louis Agassiz and George Berkely." The titles are quoted in full, inasmuch as it will be recognised that the author's arrangement is unusual, both as regards treatment and the choice of some of the subjects. The same observation is true of the separate lectures: we everywhere meet with interesting views and modes of statement which are individual and original, and evidently represent the deep personal convictions of the author upon subjects to which he has devoted much time and thought. It may be questioned, however, whether the printed lecture is not an inconvenient form in which to address a wider audience than can be gathered in any hall or theatre. The spoken lecture is the best of all forms of communicating ideas, because we have the speaker's personality associated with his thoughts. But the form of a lecture is in large part determined because its substance is conveyed so easily and rapidly by speech and hearing. The same idea must often be repeated in different words, in order that it may be grasped and remembered before passing to others; and an argument may, and often should, be drawn out and enforced at a length which would be unnecessary and even tedious in a printed memoir. The lecturer has the great advantage that he can omit or expand according as he realises the extent to which his audience is in touch with him. When ideas are conveyed in print, the conditions are, of course, entirely different. When the reader does not fully understand, he can pause and reflect, and can read again without losing the sequent ideas. Hence the form can, and should, be far more terse and condensed, and the argument does not need the same enforcement, while the repetition so necessary in a lecture is apt to become irritating.

Allowing for these qualities, which are essential to a lecture, the chapters are most interesting and stimulating.

In estimating the life-work of Huxley, the author rightly places in the foreground the great and successful struggle for intellectual liberty.

> "To what nobler end could life be devoted than the attempt to show us how we may 'learn to distinguish truth from falsehood, in order to be clear about our actions, and to walk sure-footedly in this life.' If he has succeeded, and every zoologist who is free to follow nature wherever she may lead is a witness that he has succeeded—if, as the end of his lifelong labour, intellectual freedom is established on a firmer basis—this is his best monument, even if the man should quickly be forgotten in the accomplishment of his end. No memorial could be more appropriate than the speedy establishment of that intellectual liberty which is not intellectual licence on a basis so firm that the history of the struggle to obtain it shall become a forgotten antiquity" (p. 35).

Space prevents further allusion to the interesting criticism of Huxley's philosophy, and the statement of the particular parts of it which have proved to be of the highest value to the author.

"The interminable question whether 'acquired characters' are inherited" is not directly attacked by the author; but it is indirectly attacked in an extremely interesting and effective way. Granted that such inheritance is possible, the author inquires how far it is of value in accounting for the facts of natural history, and concludes that it is of no importance. The third lecture especially deals with this subject, although it recurs in various places throughout the volume. The discussion opens with a most appropriate reference to the teachings of Aristotle.

> "Herbert Spencer tells us that the segmentation of the backbone is the inherited effect of fractures, caused by bending; but Aristotle has shown ('Parts of Animals,' I., i.) that Empedocles and the ancient writers err in teaching that the bendings to which the backbone has been subjected are the cause of its joints, since the thing to be accounted for is not the presence of the joints, but the fitness of the joints for the needs of their possessor. It is an odd freak of history that we of the end of the nineteenth century are called upon to reconsider a dogma which was not only repudiated two thousand years ago, but was even then antiquated."

The writer warns us that the tendency of exclusive laboratory teaching may be to lead us to forget Aristotle's principle; and he devotes the whole of this most important chapter to the demonstration, from the discussion of numerous examples, that the problem of fitness is the real problem which confronts the naturalist, and that it is entirely untouched by the explanation of nature as inherited nurture. The chapter concludes with a most convincing reply to the opposing arguments of an English writer. The author unfortunately omits a reference to the publication from which he quotes. The same omission is to be noted in other cases, as in the quotation from Agassiz on p. 16.

In the chapter on Lamarck a powerful argument is derived from "adjustments to the life of other beings than the ones which exhibit the adjustment," such as the poison-fang or sting, which are valuable to the possessor because of their effect on other species. The author finds "the production of adaptations of this sort by the inheritance of the beneficial effects of use, or in any way except by selection, quite unthinkable." Henslow's volume, "The Origin of Floral Structures through Insect and other Agencies" (Internat. Scientific Series) does not appear to be known to the author, although by a few well-chosen examples he shows the futility of the supposed origin which is therein suggested.

> "For all I know, the Lamarckian may claim that the visits of insects have, in some way, modified the flower, to its own good, by their mechanical action, by pulling down this part, and by pushing up that, generation after generation, until they have caused adaptive modification in the flower. I do not know how much his ingenuity may be able to make out of this hypothesis; but no one can believe that the hooks and spines, which are so obviously adapted for distributing burrs and seeds, by fastening them to the fur of passing mammals, have been produced by the inheritance of the effects of this sort of mechanical contact; for these structures do not come into use until they are dead; and, most assuredly, dead things cannot transmit 'acquired characters' to their descendants. When a drop of rain or dew falls on the dead, dry, twisted glume of the animated oat (*Avena sterilis*), it untwists in such a way as to push like the leg of a grasshoper, and, raising the seed, to send it off with a jump. After the seed has fallen, this process is repeated again and again, until the heavy end, where the seed is placed, falls at last into some roughness in the ground, when the glumes begin to kick and to struggle, and, catching in the grass and roots, or on the rough ground, to push the seed down and to plant it. The seed is alive, but the glumes are dead and dry, and as completely out of the line of descent to future generations as the dead leaves which drop from the tree."

This quotation illustrates the very effective manner in which the Lamarckian principle is dealt with. In certain striking cases it is shown to be obvious that the hypothesis of Lamarck *cannot* supply an explanation, while selection offers a probable solution. At first sight these examples may appear to be exceptional and rare, but the author shows us that

> "all the adaptations of nature are of this sort. *In all cases*, the structure, habits, instincts and faculties of living things, from the upward growth of the plumule of the sprouting seed to the moral sense of man, are primarily for the good of other beings than the ones which manifest them."

In support of this conclusion, the evidence of "the insignificance of the individual, as compared with the welfare of the species" is marshalled and illustrated in a peculiarly convincing and striking manner. Of all the examples, the most wonderful is certainly that of the queen-bee in her relation to the other members of the royal family and to the hive. A hive requires a queen, but would be disorganised by the presence of more than one queen at the same time. Until the queen-mother has led out a swarm, the workers will not permit a young queen, although mature, to leave her cell. In order to preserve her from the reigning queen, she is walled up with layers of wax and fed through a small opening. When swarming has occurred, a young queen is allowed to escape: she in her turn is impelled to kill the rest of the royal brood, but is prevented by the workers. Later on in the season, however, when it is no longer possible to swarm, the attitude of the workers entirely changes, and they now "incite her to destroy her rivals." And here we meet with a most wonderful adaptation. It is obvious that any royal larva may, under certain circumstances, benefit the hive by producing a reigning queen, or, on the other hand, under different circumstances, may be killed in order to prevent a danger to the community. The instincts of the royal larva are such that it prepares beforehand for the latter alternative, and facilitates its own murder without inconvenience or danger to the queen, by spinning an incomplete cocoon which exposes the soft abdomen to the sting. Darwin pointed out in the "Origin of Species" that the social Hymenoptera afford the most complete evidence of instincts which cannot be due to use-inheritance inasmuch as they are exhibited by the sterile workers, the offspring of drones and queens with quite different instincts. Brooks has used the same example with great effect to emphasise "the supreme importance of the species, and the relative insignificance of the individual." Darwin's conclusion is also put with remarkable force on p. 95. This most interesting and convincing chapter concludes as follows:

> "Some may ask whether it may not be possible that while natural selection is the chief factor in the origin of species, there may still be a residuum to be accounted for by the 'inheritance of acquired characters.' For all I know this may be not only possible, but actually the case. I have never felt the slightest interest in *a priori* demonstrations of the impossibility of this sort of inheritance; and for all I know to the contrary, proof of its occurrence may be found at any time, although I know no good evidence of its occurrence. I had satisfied myself, long before the recent revival of interest in the matter, that whether it be a real factor or not, the so-called Lamarckian factor has little value as a contribution to the solution of the problem of the origin of species; and renewed study has strengthened this conviction."

It must be remembered, on the other hand, that such inheritance would require an inconceivably elaborate mechanism, which can hardly have arisen and been sustained in order to account for a factor which is of little value in evolution.

"Migration in its bearing on Lamarckism" is the title of the succeeding lecture. The same subject was treated of in one of the most fascinating of Wallace's classical essays upon natural selection. It is interesting to compare the two, and to recognise how very greatly the interpretation of this difficult problem has been elucidated by the younger zoologist. Wallace dwells upon the lines of bird migration in their relation to past geographical change, and to the special need for insect food during the breeding season. Brooks treats the problem as a part of the wide principle of the subordination of the individual to the welfare of the species; he doubts the dependence on geological change and the great importance of food, and makes the illuminating suggestion that security from the enemies of eggs and young is the controlling factor alike of bird and fish migration, and he dwells on the risk to parents involved in the process.

> "Long journeys are hazardous. Every Californian salmon which enters upon the long journey to the breeding ground is destroyed, and the whole race is wiped out of existence for the good of generations yet unborn. Very few shad ever return to the ocean, and storm and accident and ruthless enemies work their will on the migrating birds and decimate them without mercy; yet the dangerous return to safe breeding grounds still goes on, in order that children which are yet unborn may survive to produce children in their turn."

Want of space prevents any further criticism of this most interesting volume. Enough has been said to prove that all the lectures demand the serious consideration of every student of evolution.

It is a peculiar pleasure to the British naturalist to find the Darwinian principle illustrated and defended with such remarkable force and success by a distinguished American zoologist. E. B. P.

## A MODERN TEXT-BOOK OF OPTICS.

*Lehrbuch der Optik.* Von Dr. Paul Drude, Professor des Physik au des Universitat Giessen. Pp. xiv + 498. (Leipzig: Verlag von S. Hirzel, 1900.)

PROF. DRUDE'S name is well known to English physicists. As a careful and exact worker, the author of a book on the Physics of the Ether, and the successor of Gustav Wiedemann in the editorship of the *Annalen des Physik*, he has already made a high reputation for himself, and the book now under consideration will serve to add to it. Text-books of optics, it is true, are numerous, and the reviewer is apt to think that of the making of many books there is no end. Prof. Drude's book, however, contains much that is novel—at any rate, to English text-books—and the student will find up-to-date information on many points of interest.

In some respects the book has much in common with the late Prof. Preston's well-known text-book; it gains, however, in the end as a treatise on the subject by the definite adoption of the electromagnetic theory, although it is, of course, in consequence, less complete in that it gives no account of elastic solid theories.

The first hundred pages deal with geometrical optics. After a clear statement of the fundamental laws, including the law of the minimum path, and Malus' law of orthotomic systems, we have a chapter on the geometrical theory of optical images. A definition of an optical image is given; it is then shown that the image of a plane is a plane, and hence the analytical relation between the position of a point and its image is found. From this, following Abbé and Czapski, the geometrical theory of a perfect image is developed clearly and concisely. Throughout this part the book runs on similar lines to Dr. Moritz von Rohr's "Geschichte des Photographischen Objectivs," recently reviewed in these pages (NATURE, vol. lxi. p. 511), though, of course, the more technical part is dealt with much more briefly than in Dr. von Rohr's book.

Further chapters deal with the formation of images by real rays and the effects produced by the limitations in the size of the pencils in the case of actual instruments. The chapter on optical instruments is perhaps rather brief, but it is not the main object of the author to describe these. Throughout this part the book is very different from anything yet published in English, and will well repay study; it is interesting to read and clearly written; at the same time, it is commendably brief, and contains little long or cumbersome analysis.

The remaining four hundred pages are devoted to physical optics. In the first section of this, which deals with the general properties of light, there is, with one exception, nothing particularly novel. The treatment of interference, diffraction, the geometrical theory of double refraction and the colours of polarised light follow the usual lines; it could hardly be otherwise. The whole is brought up to date, however; there is, for example, an excellent account of Michelson's echelon spectroscope, while the theory of the resolving power of an optical instrument is given in some fulness; it is all well done, though the English reader will not find much to make him prefer the book, as a text-book, to Preston. The one exception is the chapter on Huyghens' principle. In his elementary discussion on the rectilinear propagation of light, Dr. Drude makes a distinct step by adopting the methods given by Dr. Schuster (*Phil. Mag.*, vol. xxxi. 1891), while he completes the discussion by giving Kirchhoff and Voigt's solution of the problem of finding the disturbance at a given point due to disturbances existing at some previous time over a surface surrounding the point. To do this, he has, of course, to make use of the differential equation satisfied by the disturbances, and this is not found till a later stage in the book; but the student who has read sufficient mathematics to follow the proof will probably be acquainted with the fact that the differential equation quoted does represent wave motion, and will not find any logical difficulty in the order adopted, while the proof will put the whole theory of diffraction before him on a sounder basis. An English reader, however, who realises what he owes to Stokes in this matter, may be allowed to express surprise that there is no reference in Prof. Drude's work to the great paper on the dynamical theory of diffraction, published in 1849 in the ninth volume of the *Transactions* of the Cambridge Philosophical Society.

The second section of this part deals with the optical properties of bodies, and here the distinctive points of Prof. Drude's method show themselves. After a brief reference to the elastic solid theory of the ether and the difficulties to which it leads, he adopts formally the electromagnetic theory.

The optical disturbance at any point through which light-waves are passing can be represented by the periodic variations of a vector quantity, the light-vector, as Drude calls it, and in a transparent isotropic medium this vector follows the same laws as do the electric or magnetic force in an insulating body. The electromagnetic theory of light identifies the light vector either with the electric or the magnetic force. Drude adopts the first of the two alternatives.

In an æolotropic medium, a third vector, the rate of change of the electric displacement, or the electric current, needs to be considered—in an isotropic body this coincides in direction with, and is proportional to the electric force. For reasons which are stated, however, in a crystal, this third vector, the electric current, is taken to represent the light vector. The consequences of this theory are then worked out fully. The general equations of the electromagnetic field are obtained from the two laws (1) that the work done in carrying a unit magnetic pole once round an electric current $i$ is $4\pi i$; and (2) that the work done in carrying a unit quantity of electricity once round a magnetic current $j$ is $4\pi j$.

The phrase magnetic current is perhaps not a very common one, though some English writers have used it. The magnetic current multiplied by $4\pi$ is equal to the rate of change of magnetic induction; thus the second law is merely Faraday's law of induction of electric currents.

In forming the equations care must be taken to measure throughout in the same units, electrostatic or electromagnetic, as the case may be. Prof. Drude assumes that electric inductive capacity and permeability have no dimensions and introduces a quantity, which he tells us is of the dimensions of a velocity and equal to the velocity of light, as representing the ratio of the units. The same result would have been reached more simply by introducing two symbols, $\kappa_0$, $\mu_0$, of unknown dimensions to represent the inductive capacity and permeability of a vacuum, and then showing that $1/(\kappa_0\mu_0)^{\frac{1}{2}}$ was of the dimensions of a velocity.

From the equations thus found, together with the known electromagnetic laws expressing the action which takes place at the common surface of two media, the laws of transmission, reflexion and refraction in isotropic and crystalline transparent bodies can, as is well known, be deduced so long at least as we avoid phenomena of dispersion. They lead to Fresnel's sine and tangent laws for reflexion, and these in reality are not accurately satisfied; but it is shown that the small amount of elliptic polarisation observed can be accounted for by the supposition that the transition across the interface is not sudden. On this point a reference to a paper in the *Phil. Trans.* for 1894, Part ii., by G. A. Schott, would not have been misplaced. In fact, we may say that so long as the difference between the properties of a refracting body and those of the ether can be completely expressed by a change in the inductive capacity, the simple equations of the electromagnetic field suffice for the co-ordination of optical effects; but when this is no longer the case, when the supposition of a mere change in refractive index is not sufficient to express the action of the matter upon ether, modifications in the equations which can not be entirely justified by reference to known electromagnetic laws become necessary. Absorption and dispersion, aberration and the action of magnetism on light require further hypotheses for their explanation, and the part of the book in which Prof. Drude deals with these and cognate phenomena is of great interest.

The phenomena of absorption and of metallic reflexion are explained by the hypothesis that absorbing media are conductors like the metals.

The total current in such media is composed of two parts, that of displacement or polarisation depending on the rate of change of the electric force, and that of conduction proportional to the force. From this it follows that in the equation for a component of the electric force, X, for example, a term in $a\mathrm{X}/dt$ appears; we have a viscous as well as an elastic resistance to the motion.

Prof. Drude points out, as Lord Rayleigh had done nearly thirty years before (*Phil. Mag.*, 1872), that the numerical results derived from experiments on the metals cannot be reconciled with such a simple theory; it needs modification, and the direction of the requisite change is indicated by the theory of dispersion which is discussed next.

Up to this point the theory has not been mechanical. We know from purely electrical observations the laws of electromagnetic force without needing to know the mechanism, ætherial or material, to which that force is due. Changes in the electric force give rise in a dielectric, to an electric current, Maxwell's displacement current, and the laws obeyed by this current in transparent bodies are exactly those of light.

The light vector may be electric displacement, or it may be some periodic change in the ether, *e.g.* a twist or a displacement of the ether particles, which obeys exactly the same laws as electric displacement; we do not know, and, so far as the theory is concerned, we do not need to know, which of these hypotheses is true.

When we are dealing with the action of matter, however, it becomes necessary to introduce some mechanical conceptions. Thus Prof. Drude, following von Helmholtz, supposes that the molecules of a dielectric are composed of charged ions which are set in motion by the electric force when a train of light waves traverse the medium. The current in this case across any section is made up of the displacement current, together with the convection current due to the displacement of the ions; thus a new variable, expressing the displacement of the matter, is brought into Maxwell's simple equations. In consequence a new set of equations, determining the motion of the ions, become necessary.

Now, the external force on an ion will be proportional to its charge and to the electric force. Drude supposes that, in addition, its motion is retarded by a force proportional to its displacement, and by a frictional force. Of course, since we are dealing only with harmonic motion, this is merely equivalent to saying that the force of restitution can be expressed by a series of harmonic functions. In this way equations are obtained similar to those given by Sellmeyer's mechanical theory—a theory, as Lord Rayleigh has recently shown, originally due to Maxwell—from which the phenomena of dispersion can be deduced. The same hypotheses serve to overcome the difficulties of a theory of metallic reflexion based on conductivity.

Fairly obvious modifications of the equations of motion of the ions lead to explanations of the rotatory polarisation of sugar and quartz. The action of magnetism on light is more complex; it is deduced from an hypothesis of molecular vortices. The ionic charges are supposed to be in a state of rotation about the lines of magnetic force, and the consequences of this on the equations of motion are examined. This leads to a rational explanation of the magnetic rotation of the plane of polarisation, and of the Hall effect, while in another section the Zeemann effect is touched on. The last chapter of the section deals with aberration; it is supposed that the ether in a moving body remains, so far as the motion of the body is concerned, at rest. Thus another term has to be added to the expression for the current; the ions are carried with the body, and give rise to a convection current.

This assumption appears, however, open to criticism. Since the total charge in any element of volume is zero, the total convection current due to the motion of that element, as a whole, must also be zero. The case differs from that in which the oppositely charged ions are set in motion in opposite directions by electric force. The fact that the axes to which we refer the relative motions of the ions are themselves in motion, introduces new terms into the equations which are sufficient to account for aberration without assuming the existence of this convection current.

The consequences of this relative motion are examined, following H. A. Lorentz, to whose labour on this subject so much of our knowledge is due, and an explanation given of aberration and of Fizeau's celebrated experiment on the effect of moving water on the velocity of light.

In all this work Prof. Drude has been most successful; the electromagnetic theory, supplemented by the one additional hypothesis of the moving ions, serves to coordinate in a satisfactory way very many of the phenomena of light.

Further knowledge may modify our views, but up to the present Prof. Drude's book contains the most rational account of the phenomena of optics which we possess; it is a book which should be read by all students, and he is to be congratulated on having written it.

And now having said this, in conclusion a grumble and a suggestion may be permitted. There is no index, and though the table of contents is a full one, this can never replace an index. Again, the book would be more interesting and more valuable, and would give a fairer account of the subject, if the references to original papers, especially papers published some time back and in other countries besides Germany, were more complete. A second edition will be called for before long. Will Prof. Drude increase the gratitude due to him for his work by remedying these two defects?

---

## *AGRICULTURAL EDUCATION IN THE UNITED STATES.*

*Year-book of the United States Department of Agriculture,* 1899. Pp. 880; 63 plates. (Washington: Government Printing Office, 1900.)

THE present volume is a special one, the Secretary of Agriculture desiring "that the Year-book for 1899, the distribution of which will occur during the last year of this century, shall present to the reader a picture of the development of agriculture in the United States during the nineteenth century, and of its condition at the present time." The volume contains twenty-six reports, from the various bureaux and divisions under the Department of Agriculture. These reports are followed by an appendix giving particulars respecting the various agricultural organisations now at work in the country. The whole is copiously illustrated.

The various reports on the development of knowledge and of work during the past century are of course written in a popular style, being primarily intended for the information of the general community in the United States; we must not, therefore, expect to find in them much exact science. They are, nevertheless, of great permanent value, and should be carefully studied by all those who desire that the agriculture and the agriculturist of Great Britain should exhibit the rapid progress in improvement which this volume shows to be taking place on the other side of the Atlantic.

As the subject of agricultural education is now occupying the public mind in England, it will perhaps be of service if we briefly mention what is at present being done in America, as set forth in the volume now before us.

The Report dealing with education informs us that the attempts to introduce instruction in agriculture into elementary rural schools have failed. Now, however, a hopeful movement has been started by the College of Agriculture at Cornell University, and taken up by some other State colleges, for the introduction of "nature studies" into elementary schools. To accomplish this object leaflets containing suitable matter for lessons have been issued, and model lessons are given in the schools by travelling inspectors. The first difficulty to be surmounted is, in fact, the teaching of the teachers. Up to the present time little has been done toward the establishment of second grade agricultural schools, and agricultural subjects are not as yet taught in the High Schools.

In America, the State College or University, with the Experiment Station attached to it, have been the prime movers in agricultural education. The colleges have by no means confined their work to their own students, but have actively carried on a large amount of external teaching of various kinds. Thus, besides the full course of instruction, lasting two or four years, provided for the members of the college, short winter courses of twelve weeks' instruction are in many cases provided for the special requirements of young farmers, and in some States these short courses have been very successful. The staff of the college and experiment stations also do much good by lecturing at farmers' institutes. These institutes will meet for a session of three days in various places, the time being occupied by a series of papers and discussions. It is estimated that about 2000 of these meetings were held in the United States during 1898, attended by half a million farmers. In Wisconsin the best papers are issued as an annual volume, 60,000 copies of which are distributed, one being placed in the library of every elementary school. The practical influence of these institutes has been very great. Several State colleges have also commenced correspondence classes in agriculture, and have enrolled a large number of readers who receive assistance and advice from the college. The influence of the experiment stations has also been very great; their investigations have produced a local interest in the study of agricultural problems, and afforded examples of the aid which science can render to the farmer. Without the work of the station the teaching of the college would have appeared academic and theoretical, and would have failed to commend itself to the practical man. The farmer's bulletins issued by each experiment station, and distributed post-free throughout the State to every farmer asking to receive them, are of considerable educational value. The work of all the State colleges and experiment stations is unified by the Association of American Agricultural Colleges and Experiment Stations. This Association consists of delegates appointed by the colleges and stations, and by the United States Department of Agriculture, and meets for several days once a year to hear reports and discuss methods of work. The Association has permanent executive committees, which carry out the work initiated by the Association.

Although both colleges and experiment stations are State institutions, they are more or less under the influence of the National Department of Agriculture, as every institution receives annual grants from Government funds, for the proper use of which the Department of Agriculture is made responsible. The United States Department of Agriculture is on a very large scale; the sum appropriated to its use by Congress in 1899 was 2,829,702 dollars. It includes many sub-departments, provided with a numerous staff of scientific workers. It has excellent laboratories, a botanic garden, museum and library containing 68,000 volumes, three-quarters of which are on agricultural subjects. It undertakes investigations of all kinds. It publishes in the *Experiment Station Record* summaries of all the work done by the experiment stations. The publications it issues for gratuitous circulation are most voluminous, and embrace all subjects with which it is thought the farmer or student should be acquainted. In 1899, 26,420 pages were published, and 7,075,975 copies printed. Of the present year-book the edition is 500,000 copies, with 20,000 extra copies for the Paris Exhibition.

We have already mentioned the sum annually spent by Congress on the Department, we may conclude by saying that the annual income of the State agricultural and mechanical colleges is stated in the year-book to be 6,008,379 dollars, while the income of the experiment stations amounts to 1,143,334 dollars. Such is in brief the provision made in the United States for the improvement of the science and practice of agriculture in the country.

R. WARINGTON.

## *OUR BOOK SHELF.*

*Lehrbuch der Anorganischen Chemie.* Von Dr. A. F. Holleman. In gemeinschaft mit dem Verfasser bearbeitet und herausgegeben von Dr. Wilhelm Manchot. Pp. xii + 440. (Liepzig: Veit and Co., 1900.)

THIS is an advanced text-book of inorganic chemistry, distinguished from others chiefly by the embodiment in it of chapters of modern physical chemistry. The book, indeed, gives the impression of having been produced by shuffling the detached chapters of two others—one, an ordinary treatise on inorganic chemistry, the second on physical chemistry.

It is almost impossible to discern the system which has guided the compilers. The book begins with some generalities about the scope of science, and the differences between physics and chemistry. It then proceeds to describe some chemical operations, such as dissolving, filtering and distilling. This is done in language suitable for children, and illustrated by two diagrams, in one of which a filter paper is seen to project considerably above the rim of the funnel. The elements having been named, oxygen is next described—such terms as critical temperature being taken as understood by the reader, who has just been told how to separate salt from sand. After a description of hydrogen, the indestructibility of matter is discussed, and then comes water. The laws of chemical combination and the atomic theory occupy the next few pages, then chlorine and its compounds. We now come upon the laws of Gay Lussac and Avogadro, ozone and hydrogen peroxide, then modern methods of determining molecular weights, with a discussion of semi-permeable membranes. And so the book proceeds. Dissociation is discussed between iodine and fluorine, electrolytic dissociation between the halogens and sulphur, the phase rule under sulphur, thermochemistry, including thermodynamics between sulphur and nitrogen.

It is impossible to say anything in praise of this arrangement or want of arrangement. It can hardly be defended on logical or didactic grounds, and one is tempted to think that there is nothing more than a striving for novelty at the bottom of it.

The book does not aim at teaching how chemists do their work, discover facts, and establish theories; and surely if it were desired to present descriptive inorganic chemistry on the basis of the general theories of modern physical chemistry, it would have been better to have begun with an account of these theories and to have woven them into the descriptive part throughout.

Whilst speaking thus of the general scope of Prof. Holleman's book, it is right to add that in detail there are features that call for commendation. The descriptive part is well abreast of the times, and many of the intercalated chapters on physical chemistry are clearly and concisely written. A concluding chapter summarising Werner's voluminous papers on the metal-ammonium compounds is a valuable addition.

On the whole, it may be said that as a work of moderate dimensions conveying the chief facts of inorganic chemistry and an account of those physico-chemical theories which bear especially on inorganic chemistry, Prof. Holleman's book will probably find considerable acceptance in Germany, but it is neither to be expected nor desired that it will set a fashion in its plan of construction.

A. S.

*Flora of Bournemouth, including the Isle of Purbeck.* By E. F. Linton, M.A. With map. New edition. Pp. vii + 290. (Bournemouth: Sold by H. S. Commin, Bright's Stores, and W. Mate and Sons.)

THE local flora embodied in the pages of the book before us appears to be usefully compiled, though perhaps the volume as a whole would have been improved had it been printed on thinner paper, so as to form a more convenient pocket companion. Opening with a short introduction on the physical and geological characters of the district, the author gives a list of some 1137 plants (flowering plants and ferns) as occurring within the area treated of, and adds localities, as is usual in works of this nature. The book should prove useful to those lovers of wild flowers who are visiting the Bournemouth district, to many of whom it may perhaps be a matter of surprise that so large a percentage of the British flora occurs within a twelve-mile radius from the town.

*Carnations and Picotees for Garden and Exhibition.* By H. W. Weguelin, F.R.H.S. Pp. viii + 125. (London: George Newnes, Ltd., 1900.)

THIS is a book which will be useful to those who are fond of carnations. The cultural hints are clear, and lists are given of many of the best sorts. The text is a little diffuse in places, but in a work of this character that is a pardonable characteristic. The author is enthusiastic on his subject, and his book is worth reading, if only to show what can be done with the flowers as materials for open borders.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Collateral Heredity Measurements in Schools.

As a result of the appeal, made in NATURE last June, for aid in the measurement of pairs of brothers and sisters, I have received friendly help from a number of masters and mistresses up and down the country. I think I have received between 400 and 500 data forms properly filled in. Considerable as this assistance has been, I would still beg for further aid, as I want the collection to reach, if possible, 1000 pairs for each fraternal relationship. I have at the present time several head-spanners free, and shall only be too glad to send one to any teacher who will undertake the necessary observations on six to ten pairs of brothers or sisters. As I said in my former letter, the determination of the intensity of hereditary resemblance is a very important matter, and it can, at any rate in the case of man, only be achieved by co-operative effort on the part of those interested in science. KARL PEARSON.

University College, London, October 9.

### The White Rhinoceros on the Upper Nile.

It may interest your readers to learn that during his recent notable traverse of Africa from South to North, Major A. St. Hill Gibbons shot on the Upper Nile, near Lado, a rhinoceros which he considered to be the white or square-mouthed rhinoceros (*R. simus*), hitherto only known from south of the Zambesi, and now, unhappily, nearly extinct there. His determination is fully borne out by the skull, which I have had the pleasure of examining, and which shows all the many characters that distinguish *R. simus* from the common species, *R. bicornis*.

That a rhinoceros of this group existed in Central Africa has been suspected before. Dr. Gregory in "The Great Rift Valley," mentions having seen in Leikipia, but failed to shoot, three specimens which he believed to be *R. simus*. Some years earlier Count Teleki shot a "White Rhinoceros" in the same district, but his account has more reference to the colour than to the specific determination of the animal, and his specimen may only have been a pale-coloured *R. bicornis*.

Now, however, Major Gibbons has fortunately set the matter at rest, as there can be no question that his animal is not *R. bicornis*, but belongs to the rarer southern form, hitherto supposed to be practically extinct.

The discovery of this animal in the Nile watershed brings it geographically nearer to its European and Siberian ally, the Pleistocene *R. antiquitatis*, both species being in turn, no doubt, offshoots of the Pliocene *R. platyrhinus* of the Siwaliks.

Natural History Museum, OLDFIELD THOMAS.
October 12.

P.S.—This find has an interesting parallel in Mr. W. Penrice's discovery in Angola of a zebra allied to the true Cape Zebra (*Equus zebra*), now also nearly extinct there. But in that case the species proves different by its shorter hair, and much broader white striping, and has been named *Equus penricei*.

### Disease of Birch Trees in Epping Forest and Elsewhere.

In Epping Forest, and in other districts around London, birch trees have been attacked during the late summer by a disease which causes them to die very rapidly. In a portion of the Forest known as Lord's Bushes, thirteen diseased and twenty-four completely dead trees were noted on June 10 within an area of about one and half acres.

A few were attacked in the Forest in the summer of 1899, but it was not till this year that the disease appeared in such a destructive form. On Chiselhurst Common, Hayes Common and Keston Common no signs of the disease were evident in the early summer, but now dead or diseased trees may be found in great numbers. Trees attacked in a similar manner occur at Walton-on-Thames, by the canal between Weybridge and Woking, at Lewisham and at Westerham.

The disease is probably due to a micro fungus, *Melanconis stilbostoma*, Tul., for it appears on the branches of both living and dead trees. The diagnosis of the disease is almost precisely that of *Valsa oxystoma*, described as the destroyer of *Alnus viridis* in some parts of the Tyrol.

It would be interesting to know if any of your readers have observed the disease in the Midlands or in the north of England. ROBT. PAULSON.

10, Denholme Road, Maida Hill, October 8.

### Sunspots and Frost.

In the study of winter cold, we find, I think, some striking contrasts associated with different parts of the sunspot-curve. These contrasts, whether they are really due to sunspot variations or no, seem worthy of attention as a practical matter, and an occasion for observing whether such relations are maintained in future.

Taking the Greenwich records since 1841, let us see how many frost days there were in each three-year group following the sunspot maxima 1848, 1860, 1870, 1883 and 1893; and how those sums are related to the average (which is 164 in three years). The following table shows this:—

| Three-year groups | *a*<br>Frost days | Relation to average |
|---|---|---|
| 1849–51 | 147 | −17 |
| 1861–63 | 118 | −46 |
| 1871–73 | 131 | −33 |
| 1884–86 | 160 | − 4 |
| 1894–96 | 133 | −31 |
|  | 689 | −131 |

Thus, each of those three-year groups was mild, in respect of frost days, and there was a total deficiency of 131 days.

Now, let us do the same with the three-year groups following the minima, 1843, 1856, 1867, 1878, 1889:—

| Three-year groups | *b*<br>Frost days | Relation to average | *c*<br>*b* − *a* |
|---|---|---|---|
| 1844–46 | 166 | + 2 | +19 |
| 1857–59 | 180 | +16 | +62 |
| 1868–70 | 170 | + 6 | +39 |
| 1879–81 | 210 | +46 | +50 |
| 1890–92 | 201 | +37 | +68 |
|  | 927 | +107 | +238 |

In this case, each three-year group is over average, and the total excess is 107 days. The added column (*b* − *a*) shows that the three-year groups after minima had altogether 238 frost days more than the groups after maxima, giving an average of 47·6 for each pair of groups compared.

If we group together the fourth, fifth, sixth and seventh years after maxima (*i.e.* '52–55, '64–67, '74–77 and '87–90), and count the frost days in those four-year groups, we find that the latter share the character of the three-year groups after minima, each having an excess of frost days over the (four-year) average. We are now in the last year of another of these groups (viz. 1897–1900).

Analysing those mild three-year groups after maxima, we find out of a total of fifteen years only four with more than the average of frost days, and only one group (1884–86) in which two of the three years had an excess.

It occurred to me to examine what kind of summers we had in those mild groups, and the following curious table was arrived at:—

|  | M.T. Summers. | Relation to average. |
|---|---|---|
| 1849–51 | 61°·2 | av. |
| 1861–63 | 60·4 | − ·8 |
| 1871–73 | 61·7 | + ·5 |
| 1884–86 | 61·2 | av. |
| 1894–96 | 61·6 | + ·4 |

Thus, the divergence from the average never gets beyond a decimal value. Analysing, one finds only three of those fifteen summers in which the divergence gets beyond a decimal value (viz. −2·4, −1·1 and +1·4). The summers of three-year groups after minima might be shown to have a distinctly opposite character. But I do not lay stress on this.

ALEX. B. MACDOWALL.

### Simple Experiments on Phosphorescence.

In consequence of reading your note in NATURE of September 27, on M. Gustave le Bon's paper on various forms of phosphorescence, the following experiments were tried. A surface, previously dark, of the sulphide of calcium, was exposed to the radiation of a blackened vessel of boiling water; this gave no decisive result.

On repeating the experiment with a smoothing iron at the temperature ordinarily used, the surface in about a minute glowed brightly. There is this difference from the excitement by bright daylight, or gaslight, that the glow is comparatively transient.

This renders it probable that a cylinder of iron heated by a spirit flame duly concealed would act as M. le Bon's dark lamp does. A. M. M.

## *MEXICAN SYMBOLISM.*[1]

A RESIDENCE for some years among the Huichol Indians of Mexico has enabled Dr. Carl Lumholtz to enrich ethnology with a wonderfully detailed and exhaustive memoir on their symbolism, and our thanks are due, not only to the author, but to the authorities of the American Museum of Natural History for the appearance of this most valuable study, which is lavishly illustrated by more than three hundred figures in the text and four plates, three of which are coloured heliotypes.

It is extremely fortunate for students of American archæology and comparative religion that the symbolism of pagan Mexican Indians should be minutely studied, as this will throw light on the meaning of the inscriptions on ancient Mexican monuments, and will afford illustrations for the comparative studies of cults.

All sacred things are symbols to primitive man, writes Dr. Lumholtz, and the Huichols seem literally to have no end of them. Religion is to them a personal matter, not an institution, and therefore their life is religious, and from the cradle to the grave wrapped up in symbolism. From their symbolism it may be inferred that the main thought of their prayers is food—corn, beans and squashes. Even in the hunting of the deer, the primary consideration is that the success of the chase means good crops of corn. Agriculture depends upon rain, therefore most of the symbolic objects express, first of all, prayers for rain, and, by implication, for food, and then prayers for health, good fortune and long life. In many cases the supplicant himself is represented on symbolic objects in the shape of a human figure or a heart; but in others the god is thus depicted.

The act of sending a prayer to a god is symbolised by attaching a representation of the prayer to an arrow, the painting of the rearshaft of the arrow is symbolic of the special deity to whom the prayer is offered. In other cases, the prayer is directed to the god by placing the symbolic object representing the prayer to the temple of the deity, or by tying it to his chair, or placing it in his votive bowl.

Speaking in a general way, individual or personal prayers are conveyed by arrows or back-shields; these latter are symbols of the rectangular shield that the Huichol warrior wore to protect his back. The main idea of the back-shield is that it protects against the heat of the sun, and prayers expressed by it are largely for health, but also for protection against evil, sickness, accident, &c. Back-shields represent prayers of all kinds, such as prayers for rain, good crops, and even that the supplicant may have children; it should be remembered that the same mat served the warrior as back-shield and bed. Tribal prayers were mostly conveyed by the usually circular front-shields. Personal and tribal prayers may also be conveyed by "eyes." These are crosses of bamboo splints, or straw interwoven with coloured threads in the form of a diamond. The eye is the symbol of the power of seeing and understanding unknown things; the prayer expressed by this symbolic object is that the eye of the god may rest on the supplicant.

The diminutive sandals of an ancient pattern that are attached to a prayer-arrow may be taken as an example of symbolism. Such sandals are now only worn by shamans at the greatest feast of the Huichols—that which is held for the underworld. They therefore become the symbol of a prayer that this feast may come off; also that nothing untoward may happen to the shaman at this feast; but as the feast cannot be celebrated unless a deer has been killed, a pair of such sandals also expresses a prayer for luck in killing deer. In olden time only men wore sandals, which at that time were of the ancient pattern referred to; thus these sandals are also used to express a woman's prayer for a husband.

Practically the same design may be the symbol of various objects, for example, curved lines in general indicate serpents, but when there are dots between curved lines they mean ears of corn in the fields. Bands of curved lines with dots between them are the tracks of wind, rain and water in the fields. Zigzag lines stand not only for rain-serpents but also for lightning, the sea surrounding the world, hills and valleys projected on the horizon, bean plants and squash vines. A cross refers to the four cardinal points, but also signifies money, sparks, &c.

There is a further complication in the strong tendency to see analogies, even the most heterogeneous phenomena are considered as identical. For instance, the following are some of the objects that are believed to be serpents: most of the gods and all the goddesses, the pools of water and springs in which the deities live, the wind sweeping through the grass, the moving sea and ripples of water, flowing rivers, darting lightning, rain, fire, smoke, clouds, their own flowing hair, their girdle ribbons, pouches, wristlets, anklets, maize, bow, arrow, tobacco gourd, trails of men on the land—all are considered as serpents.

On reading this suggestive memoir, one is struck with the fact that the religion of the Huichols contains elements appropriate to two distinct stages of culture. In former ages their ancestors were evidently nomad hunters, who subsisted mainly on the meat of deer, which they killed with bows and arrows. Probably at this period they shot their arrows in the air in magical rites, so as to ensure the killing of deer; possibly also they attached pictographs or symbols to the arrows as messages or prayers to the gods, but this was almost certainly a later phase. On acquiring the art of agriculture, they continued the old practices for ensuring a sufficient food supply. According to the Huichol myths, corn was once deer, and at the feast preparatory to the clearing of the cornfields the Huichols drink the broth of deer-meat, which they call "making corn," and the blood of deer is sprinkled on the grains of corn before they are sown, that they may become equally sustaining, for the deer is the symbol of sustenance and fertility.

Departmental gods generally originate when a people become settled and take to agriculture. The prayer arrows would then be deposited in the houses of the gods. At this time, as at present, the moving principle in the religion of the Huichols was the desire of producing rain, and thus successfully raising corn, which now is their principal food; therefore is it that most of the symbolic objects express first of all prayers for rain and then for other blessings. Since the deer represents sustenance, it may easily be perceived why in their myths water sprang from the forehead of a deer.

There is no space to enter into the cult of that remarkable plant the "Hikuli" (*Anhalonium lewinii*), which is to them the plant of life—the life of the deer and the corn—and adds a further mystical element to this instructive transitional religion. The philosophy of life of these people may be best summed up in a statement by one of themselves. "To pray for luck to the god of fire and to put up snares for the deer—that is, to lead a perfect life." ALFRED C. HADDON.

## FURTHER INVESTIGATIONS ON XENIA IN MAIZE.

PROBABLY few botanical discoveries of recent years have aroused more interest than the remarkable observations of Nawaschin upon the fusion of one of the generative nuclei of the pollen tube with the definitive nucleus of the embryo sac. Since further investigations have rendered it not improbable that the process is of general occurrence, its bearing upon some curious phenomena met with in hybrids is of great interest as affording an explanation, not only as to how hybrid embryos, but also how truly hybrid endosperms can be produced by crossing different races of plants. De Vries' beautiful observations upon maize, which were made almost simultaneously with those of Correns, have already formed the subject of an article in this journal, and they have recently been considerably extended by some experiments conducted by Webber[1] in America. As a result of his investigations, Webber concludes, in all cases in which the hybrid corn shows a change of colour, that this is due to the endosperm alone, the translucent pericarp retaining, as might have been theoretically anticipated, the character properly appertaining to the corn of the female parent. But in a large number of instances it was found that, although the embryo on germination showed that hybridisation had occurred, there was no evidence of the transference of the qualities of the male parent to the accompanying endosperm. On the other hand, in some hybrid corns the endosperm exhibited a spotted appearance, which might even (*e.g.* when Gilman Flint was crossed with Stowell's Evergreen) be restricted to only a portion of its substance. The author suggests that the former case might be explained as being the result of failure on the part of the generative nucleus to unite with any nucleus within the embryo sac. The spotted endosperms, on the other hand, might be due to an independent segmentation of the second pollen nucleus, which had failed to unite with the polar nuclei, in which case the portion of endosperm so arising might be expected to retain the characters of the male parent.

There is no inherent improbability in such a suggestion, nor need it necessarily affect any views which may be entertained as to the sexuality of the fusion which we are (perhaps rather hastily) beginning to regard as general; the investigations of Boveri and of Hertwig respectively have shown that the nuclei of both male and female reproductive cells of sea-urchins can be made to segment by appropriate means, and even produce larvæ, and this without any preceding fusion of the sexual cells themselves.

It is clear, however, that much more investigation is required before the points raised by Dr. Webber can be cleared up, but it is to be hoped that so promising a field of research will not be left to lie fallow, although the work itself will necessarily prove arduous.

## PORTABLE GAS PRODUCERS.

AIR-GAS, as it is popularly called, consists of an admixture of ordinary atmospheric air with the vapour of one of the volatile hydrocarbons, such as pentane, gasolene or petroleum spirit. Travellers and others having called attention to the production of a natural gas in the petroleum-bearing districts, as at Baku and elsewhere, it was not long before attempts were made to imitate the workings of nature by producing from the petroleum of commerce a combustible gas. The carburetting of ordinary air by forcing a current over liquid petroleum first seems to have been proposed by Lowe in 1831, as in that year he took out a patent for his apparatus.

Air-gas producers may be roughly classified as follows:—

(1) Apparatus in which air is *forced under pressure* either through or over liquid petroleum, in which class mention may be made of the apparatus of Jackson, Müller, Weston and Maxim.

(2) Apparatus in which, on account of the danger of using large quantities of liquid petroleum, an absorbent is used to take up the hydrocarbon, either in part or entirely, the air being, as in the first case, *forced under pressure* over or through the absorbent.

Considerable commercial importance attaches to certain of the apparatus mentioned under the two classes given above, both the "Alpha" apparatus of Müller and the "Sun" apparatus of Hearson having had a considerable success, both here and in America, for the lighting of country houses and the like. It will be easily seen, however, that the necessity of having some *motive power* to actuate the current of air introduces complex mechanism which militates against the general adoption of such apparatus. This disadvantage has, however, been met by the apparatus comprising the third and last class of aero-gas generators, which possess a peculiar interest on account of their simplicity and efficiency.

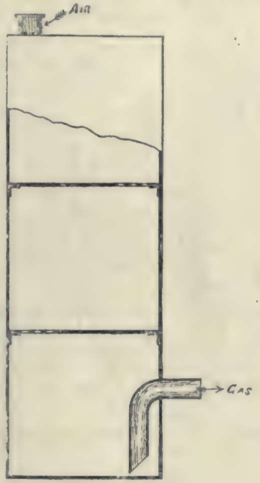

FIG. 1.

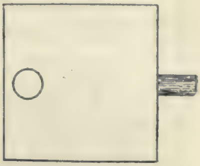

FIG. 2.

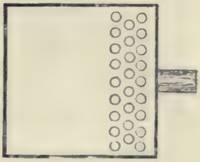

FIG. 3.

In 1895 Mr. Naum Notkin, of Moscow, was struck with the idea that use might be made of the physical property that carburetted air is considerably heavier than ordinary atmospheric air for the construction of a gas-producing apparatus of extreme simplicity. His method and apparatus, which are patented in Great Britain (No. 20667/94), may be described as follows:—

The apparatus consists essentially of a vessel of tin or other material, with an orifice at the top and another at the bottom. This simple vessel is filled with a porous material which is impregnated from time to time with one of the lighter hydrocarbons, and this constitutes the whole apparatus. The action of the apparatus is that ordinary atmospheric air enters at the upper orifice, and taking up a certain proportion of hydrocarbon vapour becomes heavier and *gravitates* through the mass of absorbents, taking up more and more of the hydrocarbon vapour, until it finally issues from the lower orifice in the form of a gas capable of lighting, heating, and all other uses to which ordinary gas is put. Not only does the gaseous mixture become heavier, but it becomes cooler by the rapid volatilisation of the petroleum, and this cooling action is greater the more rapid the passage of air through the receptacle. As the absorbents may be regarded as solids, there is no danger either from the presence of loose petroleum or of explosion.

These carburetters (or, as they are termed, aero-gas fountains), in the form best adapted for lighting and heating purposes, consist of a reservoir of ordinary tin, with an air admission regulator at the top and a bent draw-off pipe at the bottom, the pipe being so designed as to syphon out the gas and prevent the possible overflow of any loose petroleum that might be left on the bottom from an overcharge. Fig. 1 is a vertical section of such a carburetter. The carburetter is divided horizontally by two perforated shelves, the object of which is to produce a longer travel of the gas, and to distribute it through the perforations. Fig. 2 is a plan of the top of this fountain, while Fig. 3 is a drawing of one of the perforated shelves. The absorbent is a species of wood pulp which is entirely unaffected by the petroleum, and acts merely as a means of holding it in suspension.

With the carburetter as applied to table and other lamps, the burners used are argands, with steatite centre and very wide gas ways. The light is of high illuminating power and of remarkable purity. For street lighting the carburetter forms part of the lamp, which has a hinged top, so that when the carburetter is exhausted it can be lifted out and a fresh one put in its place. For ships' lights, as well as in railway and other signal lights, the system offers peculiar advantages. With respect to heating, all classes of stoves can be adapted for this system.

There is one other most important branch of lighting for which the carburetter is designed, namely, lighthouses, beacons and buoys. The advantages of gas as an illuminant were early apparent to lighthouse authorities, and in the Government inquiry into the relative advantages of paraffin, gas and electricity as sources of light for lighthouse illumination, the superiority of gas was clearly pointed out, but owing to the necessity of elaborate plant needing to be installed in the vicinity of each lighthouse to be lit by gas, it was pointed out that, despite its intrinsic advantages, it could not be recommended on account of the expense and difficulty entailed in the production. Since those days, however, the Pintsch system of vaporising oil for gas, despite its costliness both as regards the gas produced and the plant required, has been largely made use of by the lighthouse services both at home and abroad. The simple automatic carburetters that have just been described will, it is clear, place within reach of the lighthouse authorities the possibility of making use of gas-light in place of the paraffin lamps now in common use. Figs. 4 and 5 show section and elevation of a third order dioptric apparatus in which the carburetters are placed above. In place of the oil tanks required for the storing of the paraffin, the tin carburetters can be served out to the various stations ready charged, and these can be returned when exhausted and fresh ones supplied. As the absorbent takes up about three-quarters of its own volume of liquid, it is seen that the room required for storing the fountains or carburetters is little more than that needed for the present paraffin supply. As the flame given from this aero-gas is steady and constant, the trouble of maintaining the old paraffin burners of many wicks, so as to give a constant light, is obviated. By doing away with the constant level and pressure arrangements now in vogue, a considerable economy will be effected in light-house apparatus, while at the same time the risk will be lessened of a failure of some part of the mechanism.

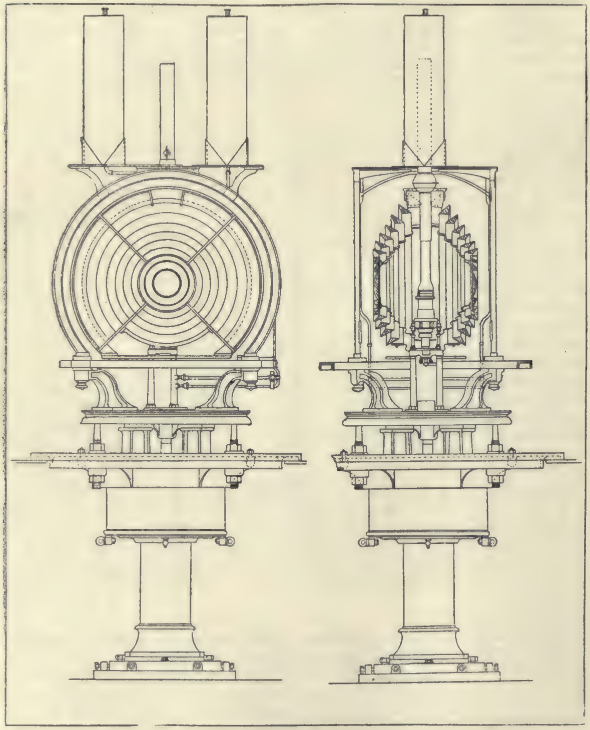

FIG. 4. FIG 5.

In their application to engines for motor-cars, launches, &c., these fountains have a very wide field of usefulness, in which they offer advantages that cannot be secured without them.

J. A. PURVES.

## NOTES.

WE regret to see the announcement of the death of Sir Henry Wentworth Dyke Acland, K.C.B., F.R.S., late Regius professor of medicine in the University of Oxford. The funeral will take place to-morrow (Friday) at Holywell Cemetery, Oxford.

PROF. T. G. BONNEY, F.R.S., has resigned the chair of geology which he has worthily occupied at University College, London, for a period of twenty-three years. The chair will become vacant at Christmas.

THE works of the late Prof. E. Beltrami (consisting of three or four large volumes) are to be issued on subscription by the Faculty of Science of the University of Rome.

A REUTER telegram from Kingston, Jamaica, states that the scientific expedition sent by Harvard University, to observe the minor planet Eros during the approaching opposition, has arrived there under the leadership of Prof. Pickering.

SIR LOWTHIAN BELL, F.R.S., has been elected president of the Institution of Junior Engineers in succession to the Hon. C. A. Parsons, F.R.S.

THE anniversary meeting of the Mineralogical Society will be held on Tuesday, November 13, at 8 p.m., when a new set of bye-laws will be recommended for adoption by the committee and council of the Society.

A REUTER telegram reports that Mr. William Zeigler, a wealthy citizen of New York, will supply the funds for an expedition to start early in 1901 under Mr. Evelyn Baldwin, in the hope of reaching the North Pole. The expedition will sail in two steamers.

AT the recent meeting in Paris the International Geodetic Association discussed the difference of longitude between Paris and Greenwich, with special reference to the discordant results obtained by the French and English astronomers in 1888 and 1892. General Bassot attributed the want of agreement to an imperfect knowledge of the constant of electrical transmission of the signals. The difference of longitude will be measured again next year.

A NEW departure, which should be of much assistance to lecturers, has been made by the Sanitary Institute. Frequent applications having been made to the Institute for the loan of lantern slides and diagrams for lecture purposes, the council have collected a large number of such slides relating to sanitary arrangements and appliances, diseases, &c., which can be borrowed by members and associates for lecture purposes at a small charge. A list of 611 slides at present available can be obtained from the secretary of the institute.

THE *Board of Trade Journal* says that information has just been received, by the Imperial Academy of Science, of the discovery of diamondiferous deposits on the Kamenka, a tributary of the Sanarka. This, it is reported, is the first time that diamonds have been discovered in this region, although the existence of such deposits in the neighbourhood of the Sanarka had already been indicated. It is stated that in structure and colour the diamonds found resemble those of Brazil.

THE annual general meeting of the London Mathematical Society will be held on November 8, at 5.30 p.m. The following nominations for the new council have been made:—Dr. Hobson, F.R.S., president. Lord Kelvin, Prof. Burnside, F.R.S., and Major MacMahon, F.R.S., vice-presidents. Other members:—J. E. Campbell, Lieut.-Colonel Cunningham, R.E., Prof. Elliott, F.R.S., Dr. Glaisher, F.R.S., Prof. M. J. M. Hill, F.R.S., A. B. Kempe, F.R.S., H. M. Macdonald, A. E. Western and E. T. Whittaker. The treasurer (Dr. Larmor, F.R.S.) and hon. secretaries (R. Tucker and Prof. Love, F.R.S.) are renominated. Lord Kelvin will probably not be able to give a valedictory address.

THE foundation stone of the Imperial "Limes" Museum, which is to be erected in the restored Roman fort of the Saalburg in the vicinity of Homburg, was laid by the German Emperor on Thursday last. The museum is to contain the Roman relics which have been discovered in the excavations in the neighbourhood of the "Limes Transrhenanus," the great Roman wall which extended from the Danube to the Rhine. The excavations were begun in 1873, and have brought to light many objects of great interest, which have hitherto been placed in the Saalburg Museum at Homburg. They will be removed to the new museum as soon as it is completed. The Emperor sent a congratulatory telegram in Latin to Prof. Mommsen, who was unable to be present at the ceremony.

THE Philosophical Faculty of the University of Göttingen has (says *Science*) proposed the following subject for prizes on the Benecke Foundation: A critical investigation, based upon experimental research, of those complex chemical compounds which cannot be explained upon the ordinarily received theory of valence, or can be so explained only by a forced interpretation of the theory. This investigation should specially consider how far the phenomena of molecular addition play a part in the formation of these compounds and as to whether it is possible to formulate a comprehensive theory of these complex compounds. The first prize is 3400 marks and the second prize 680 marks. Papers in competition must be written in a modern language, and be accompanied by a sealed envelope containing the name, a motto on the outside of the envelope corresponding to the same motto on the paper. They should be sent to the Faculty of the University of Göttingen not later than August 30, 1902.

IN the year 1895 the Academy of Sciences of Berlin announced the following problem for the Steiner prize:—"To completely solve any important hitherto unsolved problem relating to the theory of curved surfaces, taking into account, so far as possible, the methods and principles evolved by Steiner. It is required that sufficient analytical explanations shall accompany the geometrical investigations to verify the correctness and completeness of the solution. Without wishing to limit the choice of subject, the Academy takes the opportunity to call attention to the special problems to which Steiner has referred in his general remark at the end of his second paper on maximum and minimum in figures in a plane, on a sphere, and in space." The foregoing problem having remained unsolved up to the present, the Academy again announces it for the year 1905. For its solution a prize of 4000 marks is offered, with an additional sum of 2000 marks. Papers sent in competition may be written in German, French, English, Italian, or Latin, and must be submitted before December 31, 1904, to the Bureau of the Academy, Universitäts-Strasse 8, Berlin N.W. The result will be announced at the Leibnitz meeting of 1905. Each manuscript submitted must bear a mark or *nom de plume*, and be accompanied by a sealed envelope containing the name and address of the author, and bearing outside the corresponding mark or assumed name.

THE Society for the Protection of Birds is offering two prizes, of 10*l.* and 5*l.* respectively, for the best papers on the protection of British birds. The mode of dealing with the subject is left entirely to competitors, but among the points suggested for treatment are the utilisation and enforcement of the present Acts and County Council Orders; the modification or improvement of the law; educational methods; and the best means of influencing landowners and gamekeepers, agriculturists and gardeners, collectors, bird-catchers and bird-nesters. Essays are to be sent in by November 30. Particulars may be obtained from the hon. sec., at the Society's offices, 3, Hanover Square, London, W.

DURING the last few weeks even the scientific recluse, occupied as he mostly is in the *recherche de l'absolu*, has had forced upon him, by serious and comic papers alike, the question of electioneering cries. Perhaps, however, it will be news to him that the subject of vivisection, so-called, has been pushed into the forefront of electioneering polemics. Warning was indeed given months ago that this might be the case as is evidenced by the contents of certain letters published in Mr. Paget's book. These letters, addressed to several of Her Majesty's Ministers, threatened, in no unmistakable terms, should these officials not become anti-vivisectionists, to use against them at the next election organised opposition, which would probably prevent them being returned to Parliament by their respective constituencies. To what extent this has actually been done we have no means of knowing, but our attention has been drawn to a letter in the *North Down Herald and County Down Independent* in comparison with which the diatribes of Mr. Coleridge sink into insignificance. The interest, however, of Miss Margaret Alder's letter does not centre in its actual abuse, but in the fact that she places vivisection first among various causes which have rendered Englishmen "fit to kill, murder and rob the peaceable and pious people of South Africa." This conclusion possibly explains why during the past few months many physiologists—even those whose problems lie, for the most part, outside the field of actual animal experiments—have received daily papers and magazines in which attention has been directed by means of blue pencil to letters and articles in which the ingenuity of the pamphleteer has been used to distort the aims and results of the physiologist. Henceforth the anti-vivisectionist societies, one and all, had better be known under their true colours. They are not honest organisations sustained by conscientious thinkers, or even artistic sentimentalists, but pigmy political cliques for turning the trend of political opinion one way or another.

THE lecture session at the Imperial Institute will be opened on October 29 with a lecture entitled "The Federal Family," by Sir John A. Cockburn, K.C.M.G. This lecture is the first of a special series of eight illustrated public lectures, relating to the Australasian Colonies, to be given on Monday evenings before Christmas. The remaining lectures will be as follows:—"Golden Victoria, its scenery, geological features, and mines," by Mr. James Stirling; "Western Australia in 1900," by Mr. George Berry; "The coal resources of Victoria," by Mr. James Stirling; "The work of the Queensland weather bureau, in its relation to the natural resources and commerce of Australasia," by Mr. Clement L. Wragge; "The Australian Alps, scenery, native vegetation, and mineral wealth," by Mr. James Stirling; "New Zealand," by Mr. J. Carthcart Wason; "Sunny Tasmania for English Invalids," by the Hon. Sir Philip Oakley Fysh, K.C.M.G.

AN important addition to the British Museum (Natural History) has just been made in the form of mounted specimens of two beautiful antelopes from the swamps of the White Nile, belonging to species hitherto very imperfectly represented in the collection. They are, in fact, the first complete specimens of their kind which have ever been exhibited in England. The species are *Cobus maria* and *C. leucotis*, both remarkable for their sable hue (at least in the males), relieved by white on the ears, and also the elegant and peculiar curvature of their heavily ringed horns. Of the former species the Museum possessed the heads of a male and female presented by the late Consul J. Petherick in 1859, which are in such a bad condition that they have not been exhibited to the public for several years, while the latter was best represented by a stuffed head (also the gift of the same gentleman), which is, however, so faded that its true colours are completely lost. For the new specimens (which have been set up by Rowland Ward) the Museum is indebted to Captain Dunn, now stationed, we believe, at Omdurman, by whom they were presented. Acknowledgments are, however, also due to Captain Stanley Flower, by whom the skins were brought to this country. The specimen of *C. leucotis* is exhibited in the case devoted to new acquisitions, but, on account of its larger size, the example of *C. maria* is placed in the case in the West Corridor which will eventually form the home of both.

THE meteorological subcommittee of the Croydon Microscopical and Natural History Club has just published its report for the year 1899. It contains valuable information relating to the daily and monthly rainfall statistics for eighty stations in Kent and Surrey, together with notes relating to the temperature and weather for each month, by Dr. F. C. Bayard, the hon. sec. of the subcommittee. The observations show that the deficiency of rainfall throughout the district was about two inches. The deficit does not appear very large, but some tables showing the total departures from the average during the last ten years reveals a serious state of things. For Greenwich, for instance, the departures from the average of eighty years show a deficit of twenty-eight inches, which is practically three inches above a year's average rainfall. And again, for Surbiton, on the western side of the club's district, the departures during the same period show a deficiency of 19·5 inches, compared with an average of forty years, or a deficiency of practically only five inches below the average rainfall for a year.

THE report on the administration of the Meteorological Department of the Government of India in 1899–1900 has appeared in the same form as in previous years; the first part gives a general account of the results of the more important sections of the work of the department, and the second part gives the usual details of administration, chiefly in the form of tables. Seismological observatories have been established at three stations. The international and special cloud observations referred to in previous reports will be shortly published, with a brief discussion. The arrangements for registration of snowfall in the mountain districts and the measurement of rainfall continue to form an important part of the work of the Indian Meteorological office; monthly returns from 2300 rainfall stations were published during the year. The storm-warning work was carried out satisfactorily; ample and timely warning appears to have been given of all the more important storms. The special warnings of floods also appear to have given general satisfaction.

THE current issue of the *National Geographic Magazine* contains an article, illustrated by diagrams, on "The West Indian Hurricane of September 1–12, 1900," by Prof. E. B. Garriott, of the U.S. Weather Bureau, and another by Mr. W. J. McGee, entitled "The Lessons of Galveston." The Lessons in question are four in number, three of which are physical and one is human. The former are as follows:—1. The danger of building on sand, Galveston being founded on a sand-bank; 2. "The bank on which Galveston was built is something more than a simple heap of silicious grains and dust; it is a record of past wave work;" and "it is the duty of the nature student to interpret natural records and guard against the building on the storm records." Lesson 3 is that of coast subsidence, and, in the opinion of the author, "it is the business of the geologist to detect and weigh the evidences of subsidence or elevation of coasts, and to estimate the rates of movement for the guidance of local residents and investors, and it behoves such citizens to avail themselves of the scientific researches."

To the *Journal* of the Franklin Institute, Mr. Lewis M. Haupt, an American engineer of reputation in matters relating to river training and harbour work, contributes a paper dealing with the present condition of the navigation in the lower reach of the Mississippi, in which he advocates that the principle of reaction jetties should be applied for dealing with the contemplated improvement of the South-west Pass. The Mississippi affords an outlet into the Gulf of Mexico for 15,000 miles of navigable waterways. In the delta the main stream divides into three principal branches, and although the water is of great depth in the channel before it enters the delta, in their natural condition these channels are so shoal as only to afford sufficient depth of water for the navigation of the smaller class of steamers. About a quarter of a century ago Captain Eads entered into a contract with the United States Government to deepen one of these passes so as to give 27 feet at low water, and to maintain this depth for a fixed period. Contrary to his strong remonstrances the South Pass, the smallest of the three outlets, was selected. Through this pass, by means of two parallel training walls, the water was confined to a width of 700 feet, and by the scour thus created, aided to a large extent by dredging, a channel having 26 feet at low water was made, and has been maintained up to the present time. This contract has now expired, and the dimensions of vessels in the meantime having outgrown the channel, the Government have had to consider the question of providing a deeper waterway. The Board of Engineers to whom the matter has been referred have advised that the South-west Pass should now be improved and deepened so as to give a depth of 35 feet at low water.

THE Board of Agriculture has published its annual report for the year 1899–1900 on the distribution of grants for agricultural education and research, with statements respecting the several colleges and institutions allied and the experiments conducted. The larger portion of the funds distributed in grants by the Board consists of subventions of a general character awarded to eight collegiate centres of agricultural education in England and Wales. Subsidiary grants have also been made to three dairy institutes, and in aid of the cost of certain specific experiments undertaken under arrangement with the Board. Examinations have also been conducted under the joint auspices of the Royal Agricultural Society and the Highland and Agricultural Society of Scotland for the recently established national diploma.

MR. HAROLD WAGER reprints from the *Journal* of the Linnean Society an interesting paper on the eye-spot in *Euglena*. He finds it to consist of a mass of pigment-granules apparently imbedded in a protoplasmic matrix. The light absorbed by the eye-spot seems to act upon a swelling near the base of the flagellum, and thus to modify its movements. *Euglena* appears, therefore, to possess a very simple form of light-organ, consisting of a sensitive region—the swelling on the flagellum—and a light-absorbing pigment-spot.

IN a note contributed to the *Rendiconto* of the Naples Academy, vi. 5–7, Dr. Giuseppe de Lorenzo discusses the probable causes of the increased activity of Vesuvius at the beginning of May last. This activity assumed the form of "Strombolian" explosions audible as far away as Posilipo, by which masses of incandescent lava were hurled into the air to an altitude of about 500 metres. These explosions Dr. de Lorenzo attributes to the exceptional rainfall, which, filtering through the volcanic cone, has penetrated to the column of lava. This hypothesis appears in conformity with the observations of Spallanzani, von Rath, Dana and others, and with the experimental researches of Daubrée.

Two papers on the figure of the earth have recently appeared, one, by M. Marcel Brillouin, in the *Revue générale des Sciences*, xiv., and the other, by Ingeguere Ottavio Zanotti Bianco, in the *Atti* of the Royal Academy of Turin, xxxi. M. Brillouin discusses the different geoïdic surfaces adopted in the problem of reduction to sea level, and points out the relative advantages of the geoïds of Pratt and Helmert. Bianco's paper contains extracts from the writings of Pratt and Helmert, showing the relative part played by these investigators and by Bruns in developing the general theory of geoïdic surfaces.

THE Selborne Society's magazine, *Nature Notes*, contains in its September issue an interesting account of a mirage, seen last June over the Needles (Isle of Wight) from the opposite shore, by Captain Giles A. Daubeny. It is not uncommon when looking at a distant headland to see the appearance of a pointed nose jutting out over the water—an effect caused by the formation of an inverted image near the water-line; but in the present instance four different horizons appear to have been observed when viewing the rocks through a telescope.

THE admirable series of memoirs published by the U.S. Department of Agriculture on the harmfulness or otherwise to the agriculturist and horticulturist of the commoner birds of North America has recently been augmented by one from the pen of Mr. F. E. L. Beal, dealing with the food of the bobolink, blackbirds and grackles. This memoir forms *Bulletin* No. 13 of the Department. The bobolink is an exception to most birds in that, both at seed-time and harvest, it inflicts immense damage on the rice-crops of the Southern States. At present, therefore, the harm it does far outweighs such benefits as it may confer; but as the bird could exist perfectly well without touching a grain of rice, hopes are entertained that means may be found of checking its depredations on that crop. On the other hand, most or all of the so-called blackbirds (which are not to be confounded with the species of the same name in Europe) feed largely upon noxious insects and weed-seeds, and are therefore highly beneficial to the cultivator. Much the same may be said of the grackles. As usual, the *Bulletin* is illustrated with good figures of the species described, and the whole publication does the greatest credit to the Government by whom it is issued.

*Bulletin* No 67 of the West Virginia University Experiment Station is devoted to a communication by Dr. A. D. Hopkins on the Hessian fly in West Virginia, and how to prevent losses by its ravages. As the result of his investigations, the author finds that the date of the appearance of the swarms of this insect depends upon the latitude and altitude of the place, and he gives a formula by means of which the former may be approximately determined for any particular locality. From this the dates may be calculated at which it is reasonably safe to sow wheat in order to escape loss from the ravages of the pest. The approximate limits of the best wheat-sowing period, and also the approximate normals for the disappearance of the fly in different districts, are graphically illustrated by means of a map.

THE September issue of the *American Naturalist* commences with an interesting paper, by Miss (or ? Mrs.) Sampson, on unusual modes of development among frogs and toads. Commencing with a *résumé* of the normal mode of breeding as exemplified in the common frog, the author goes on to show how different members of the group depart from this mode of procedure. Two species, for example, the one from West Africa and the other from Brazil, deposit their spawn in nests formed of leaves stuck together, the tadpoles moving in a mass of froth, recalling that of the cuckoo-spit insect. In both these instances the spawn is deposited in the neighbourhood of water, into which the tadpoles ultimately fall; but in a tree-frog from Rio, in which the eggs are likewise hatched in a frothy mass among leaves, the larvæ actually die if they are put into water. In another Brazilian tree-frog the tadpoles frequent cracks in rocks, and adhere to the surfaces of the latter by means of an abdominal sucker. Full reference is made to the mode of development in the Surinam toad, and also to that of the marsupial frogs, in which the young are hatched in a dorsal pouch. But perhaps the most extraordinary "nursery" arrangements in the entire group are those of the Chilian Rhinoderma, in which the tadpoles undergo their development in an enormous pouch on the throat of the male. In the same journal Mr. F. Russell has a paper on cranial abnormalities in the American races, among some of whom the persistence of the frontal suture may occur as frequently as 2·9 per cent.

The October issue of the *Entomologist* contains a summary of the capture of rare British insects during the past summer and autumn. In addition to the swarms of the pale clouded yellow butterfly (*Colias hyale*), to which allusion has been already made, no less than ten examples of the Camberwell beauty (*Vanessa antiopa*) are recorded as having been taken in the south-east and east of England. Caterpillars of the death's-head moth (*Acherontia atropos*) have been extraordinarily abundant in potato crops during the season, and many other rarities are recorded.

The *Bulletin* of the American Mathematical Society for October contains a useful list of courses in mathematics announced by seventeen German universities for the 1900–1901 session.

The Department of Mines, Victoria, has issued No. 7 of the Reports of the Victorian Coal-fields, by Mr. James Stirling, the Government geologist. It consists of descriptions, with illustrations, of the fossil flora of the Jurassic beds of South Gippsland.

A simple description of the movements and obvious characteristics of the members of the solar system, and other celestial bodies, is given in Mr. W. T. Lynn's "Astronomy for the Young" (pp. 51), the second edition of which has just been published by Mr. G. Stoneman, London, E.C.

The lecture syllabus of the Hull Scientific and Field Naturalists' Club for the winter session ranging from October to March has just reached us, and gives promise of a full and interesting winter's work. Judging by the contents of the *Transactions* of the Club for 1900, a copy of which has also been sent to us, the institution is in a healthy and vigorous condition.

County floras have at present been pretty much confined to flowering plants and fern allies. We welcome the precedent set by the Yorkshire Naturalists' Union in issuing an Alga-Flora of Yorkshire, being a complete account of the known freshwater algæ of the county, by Mr. W. West and Mr. G. S. West. The present publication, which is only a first instalment, includes 208 species.

The October number of the *Contemporary Reveiw* contains two articles of scientific interest, one, by Prof. Marcus Hartog, on "Interpolation in Memory," and one by Mr. A. Shadwell, entitled "The true aim of Preventive Medicine." The current issue of the *Humanitarian* has in it a very readable contribution on "Heredity as a Factor in the Interpretation of Disease," from the pen of Prof. D. J. Hamilton of Aberdeen.

A proof of old Semitic influence in South Africa is afforded, according to K. Meinhof (*Globus*, Band lxxviii. p. 203), by the occurrence of the word "darama" or "ndalama" in various Bantu dialects for "gold." An ancient Arabic word for gold was "dirhem," pl. "darāhim." According to the phonetic system of the Bantu languages this would necessarily be transformed into "ndalama."

Mr. C. Fox-Strangways contributes some interesting notes on Spitsbergen and Iceland in the *Transactions* of the Leicester Philosophical Society for April, 1900. Having spent only a short time on these islands, the author does not claim to record much that is new regarding them, and his article is written chiefly in explanation of a series of photographs which are reproduced to accompany the notes.

The additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mrs. W. L. Gower; two Yellow-whiskered Lemurs (*Lemur xanthomystax*) from Madagascar, presented by Mr. J. B. Joel; a Common Genet (*Genetta vulgaris*), European, presented by Baron de Soutellinlio; an Alligator (*Alligator mississippiensis*) from North America, presented by Mrs. Bazalgette; a Porose Crocodile (*Crocodilus porosus*) from the East Indies, presented by Miss Gwendoline Waite; a Broad-nosed Lemur (*Hapalemur simus*) from Madagascar, four Indian Fruit Bats (*Pteropus medius*), six Starred Tortoises (*Testudo elegans*) from India, a Dusky Sloth (*Bradypus infuscatus*) from Colombia, an Illiger's Macaw (*Ara maracana*) from Brazil, two Salvin's Amazons (*Chrysotis salvini*), an Annulated Terrapin (*Nicoria annulata*), a Brazilian Tortoise (*Testudo tabulata*), an Electric Eel (*Gymnotis electricus*) from South America, four Wrinkled Terrapins (*Cyclemmys scripta rugosus*) from the West Indies, a Common Water-Buck (*Cobus ellipsiprymnus*) from South Africa, deposited; a Violaceous Night Heron (*Nycticorax violaceus*) from South America, purchased.

## *OUR ASTRONOMICAL COLUMN.*

Ephemeris for Observations of Eros:—

New Planetary Nebula.—Mr. R. G. Aitken writes to the *Astronomische Nachrichten* (Bd. 153, No 3667) announcing that the object catalogued as star BD + 83°·357 is a small planetary nebula. With the 36 inch Lick telescope the object appears to have a stellar nucleus of about 10·5–11 magnitude centrally placed in a circular nebulous envelope about 5″–6″ of arc in diameter. The complete object is about 9·5 magnitude, and its position is:—

$$\left.\begin{array}{ll} & \text{h. m. s.} \\ \text{RA.} & 12\ 29\ 10 \\ \text{Decl.} & +83^\circ\ 21'{\cdot}8 \end{array}\right\}(1855{\cdot}0).$$

Paris Observatory, Annual Report.—In his report of the work accomplished at the Paris Observatory during the year 1899, M. Loewy, the director, states that a considerable part of the time was spent in preparing for the Exposition. Special photographs on a large scale were taken of the moon about the time of first and last quarter, giving an image about 1·38m. in diameter; considerable difficulty was encountered in the preparation of the plates for these, and special mention is made of the services rendered by MM. Lumière in this matter. Among the new instruments adopted are (*a*) the mercury bath designed by M. Hamy for registering earth tremors, (*b*) a new micrometer by Gautier for measuring the chart plates, (*c*) a new form of chronograph designed by M. l'Abbé Verschaffel, director of the Abbadia Observatory. This latter has been introduced for use in the proposed new determination of the difference in longitude between Paris and Greenwich.

For the chart photographs ninety-six sheets have been issued, and the first part of the catalogue, giving the exact positions of stars down to the eleventh magnitude, will be issued during the present year. An investigation is in progress for determining more accurately the photographic magnitudes of stars. Valuable help has been given by M. l'Abbé Verschaffel, of Abbadia, who has determined the coordinates of 3700 fundamental stars of reference for the chart photographs. A fourth volume of the "Atlas de la Lune," containing seven plates, has been published, accompanied by a descriptive memoir.

M. Bigourdan has continued his study of the nebulæ, having now measured the positions and made detailed study of 6000 of them; to complete his programme of work 400 more still remain to be examined.

The small equatorial Coudé, which was the first instrument of this type, has been entirely remodelled. A new objective has been made by MM. Henry, of longer focus than the old one (5·25 metres instead of 4·22), the silvered mirrors protected more from the action of atmospheric gases, and the whole instrument encased in a thick layer of felt. These modifications have removed all the defects existing in the old telescope.

## RANGE-FINDERS.[1]

NAVAL and military authorities are agreed that for accurate shooting almost everything depends upon the range being known with sufficient exactitude. It is not surprising, therefore, that an immense amount of attention should have been devoted to methods of rapidly determining the ranges of distant objects, whether stationary or in motion. These methods may be classified as follows:—

(1) *Mechanical.*—In this method a trial shot is fired from a gun, and so far as is practicable observation is made as to whether the shot strikes the ground (or the sea) on the near or the far side of the target. The results of the observation are used to correct the next trial shot, and so on. The method is clumsy and (at all events on board ship) costly; it is inapplicable in a naval engagement where the ranges frequently alter with great rapidity, and is, of course, totally inapplicable for purposes of navigation. On the other hand, it involves the use of no instrument beyond those ordinarily used in warfare.

(2) *Flash and Sound Method.*—Here the time-interval between seeing the flash and hearing the report from one of the enemy's guns is measured by a suitable chronograph or, by starting to count at the rate of eleven in three seconds immediately on seeing the flash; the number arrived at on hearing the report will roughly give the number of hundreds of yards in the range. This method is, of course, inapplicable amid the din of a general engagement, and besides it permits the enemy to have the first shot.

(3) *Optical Range-finders.*—In the determination of a distance by an optical range-finder, *length of base* and *time* available are very important factors. Given plenty of base-length and plenty of time, a theodolite, such as is used in surveying, satisfies all the conditions except that of portability. However, *time* is usually so important a factor for military operations that the theodolite is completely excluded even for field service. If the time is restricted, but the extent of base unrestricted, recourse may be had to long-base, two-observer instruments, such as those now in use by infantry and field artillery. When both base and time are restricted, as they are on board ship—and moreover the observer's station is itself in motion—the problem becomes at once much more difficult and much more interesting. We need not then be surprised that while military range-finders are usually simple and cheap, naval range-finders are comparatively costly and complicated.

The operation of all optical range-finders depends upon the measurement, by some device or other, of the angle subtended by a known base-length at the distance to be determined, the base being almost invariably "broadside-on" to the point. Where the known base is at the target and the point is at the observer's station, the operation of determining the distance consists simply in measuring the angle subtended by the base at the point. Instruments of this class measure, say, the angle subtended by the height of a man (assumed to be of mean stature) at the observer's station, and require for their successful employment the co-operation, willing or otherwise, of the enemy, and are therefore seldom applicable under the conditions of modern warfare. Men who have returned from active service in South Africa have stated that sometimes they never saw a Boer in an engagement. Where the known base is at the observer's station, which is an essential characteristic of all range-finders of general application (the instruments previously described being in reality mere angle-measurers), the operation of determining the range consists almost invariably in swinging the base round until it is "broadside-on" to the target, and then measuring the angle subtended by the base at the target. The measurement of the angle at the target is very commonly effected by making one of the base-angles a right angle, and observing how much the other is "off" the right angle (mekometer, &c.), or else by observing how much the sum of the base-angles is less than two right angles (naval range-finder, &c.).

Since a mere enumeration of the names of inventors of range-finders would occupy the whole of the available time for a lecture, it will be necessary to restrict the selection of examples to those instruments which are, or promise to be, in actual operation for warlike purposes. Attention then will be confined to the following instruments:—

(1) The Watkin mekometer, used by our troops in South Africa.

(2) The Watkin depression range-finder, used at certain stations for coast defence.

(3) The Zeiss tele-stereoscope.

(4) The Barr and Stroud range-finder, used in the British and other navies, in coast fortifications, and to some extent in the field.

Restrictions of time unfortunately render it impossible to describe the Watkin artillery range-finder, as well as the Fiske instrument which is used to some extent by the U.S. Navy.

(1) *Mekometer.*—This instrument consists of two parts connected by a cord 25 or 50 yards long, which is kept tightly stretched by two observers, each of whom supports one of the parts. These two observers are designated respectively the right-angle man and the range-taker. The former carries a small optical square or instrument in which two mirrors are fixed at 45° so as to set out a right-angle.

The part carried by the range-taker consists practically of a box-sextant in which one of the mirrors is adjustable by means of a graduated micrometer-screw, on which the ranges are marked for the base specified, the infinity mark corresponding to the case when the mirrors are exactly at 45°. Each of the parts of the instrument carries a prominent mark in a suitable position, and the operation of taking a range on a fixed object is as follows:—The two observers supporting the instruments connected by the taut cord set themselves in such positions that the cord is nearly "broadside-on" to the target; the range-taker now stands still, while the right-angle man—by moving forwards or backwards, with the cord always taut—adjusts his position accurately, so that the image of the mark on the range-taker's instrument, seen through his optical square, coincides with the target viewed directly. He now shouts "On," when the range-taker adjusts his micrometer-screw so as to bring the mark on the other instrument into coincidence with the target, and then the reading on the graduated scale gives the range.

For objects in motion the range-taker remains steady, while the right-angle man, as far as possible, continuously shifts his position so as to keep the mark on the range-taker's instrument and the target in coincidence. In cases of rapid motion at right angles to the line of sight, difficulties are experienced in keeping continously "on," and in such cases the right-angle man shouts "On" whenever the mark passes the target, and the range-taker then seizes the opportunity of taking the range.

There are several serious objections to two-observer instruments. In the first place, they cannot be used for the measurement of the distances of sky-lines, trenches, hedges, &c., of a more or less horizontal character, with no prominent vertical features about them. Secondly, it not infrequently happens that the two observers are working on different objects altogether or on different portions of the same object, in which case an entirely fictitious range is obtained. Most important of all, they necessarily expose the range-takers. It has been stated that several casualties have occurred in South Africa among men engaged in range-finding. Under such conditions as those pertaining in South Africa, it is obviously most risky to expose men in the open. Single-observer instruments are free from all these defects.

(2) *Depression Range-finder.*—If we have a vertical base, and if the target is constrained to move in a horizontal plane, we may dispense with the right-angle man altogether. The only case where this plan can be adopted in practice is when we wish to determine the range of a ship from a hill near the coast. The base-line is now the vertical height of the observing station above sea-level, and the range is obtained very simply by observing the angular depression of the water-line of the ship. Allowance has to be made for the effect which the tides produce in varying the equivalent height of the base. Unfortunately, the water-line of a ship—especially if the waves are at all high—forms an exceeding bad object upon which to observe, and this uncertainty can only be compensated by having a very long base—*i.e.* by having the range-finder at a very considerable altitude, say 150 feet or so. We therefore cannot use such an instrument on a flat coast, nor can we use it for determining distances at night, unless we can sufficiently well illuminate the water-line of a ship by means of a search-light.

(3) *Zeiss Range-finder.*—This is the first of the two single-observer instruments which it is proposed to describe in the prescribed limits of time. The credit of the idea underlying the construction of the instrument is due to the late Herr Grousillier of the German Army, but as the firm of Zeiss, of Jena, have spent many

---

[1] An evening lecture delivered at the British Association meeting at Bradford by Prof. W. Stroud.

years in working out the details of the instrument, it will probably be known in the future by their name. In the telestereoscope of Helmholtz two parallel reflectors are placed with reference to each eye, in such a position as to produce the optical equivalent of an increase in distance between the two eyes. This increases the stereoscopic effect. In the next place, by placing a telescope before each eye (and the two telescopes may conveniently be incorporated in the frame-piece supporting the reflectors), we multiply the stereoscopic effect still further, *e.g.* if the distance between the eyes has been artificially increased tenfold by the reflectors, and if the telescopes magnify tenfold, the stereoscopic effect will be increased altogether one hundredfold. In this way immense stereoscopic solidity is imparted to the picture in the field of view.

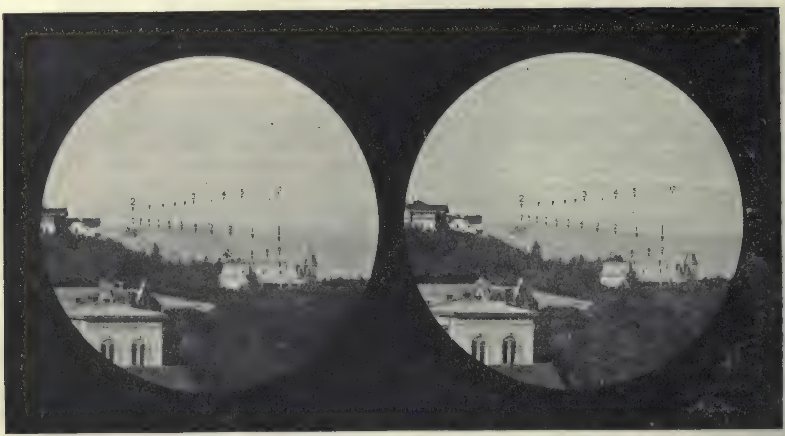

Fig. 1.—Field of view in the Grousillier-Zeiss stereoscopic range-finder.

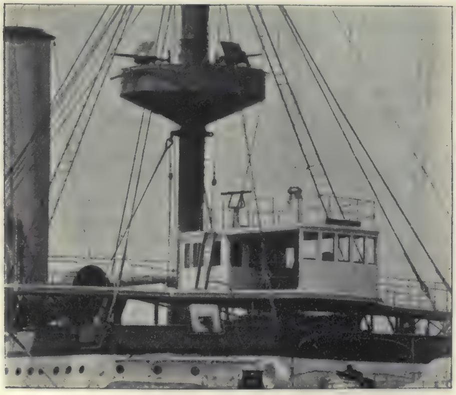

Fig. 2.—Bridge of H.M.S *Royal Sovereign*, showing Barr and Stroud range-finder on the top of the chart-house.

This instrument may be adapted to range-finding in the following way:—Suppose we imagine for the moment the instrument fixed, and that we see in the field of view of each eye the image of a pole 1000 yards away. Let permanent marks be made in the focal plane of each telescope exactly coincident with these images. Then, whenever we look into the instrument we shall apparently see a pole at a distance of 1000 yards. Let a similar pair of marks be fixed corresponding to 1100 yards, and so on. Then when we look into the instrument at a distant landscape we shall get the appearance shown in Fig. 1. If this picture be viewed stereoscopically we shall obtain a mental impression as to the distance of any part of the landscape by comparison with the marks, and in this way get its approximate range. The instrument is highly ingenious and very pretty, and it will no doubt offer a solution of the problem of military range-finding should it prove sufficiently accurate in practice.

(4) *B. and S. Naval Range-finder.*—This instrument, with a base of 4½ feet, has been adopted in her Majesty's Navy, and nearly all the larger ships are now equipped with one or more of them. Fig. 2 shows a view of the charthouse of H.M.S. *Royal Sovereign*, on the top of which the range-finder will be seen near the Kelvin compass.

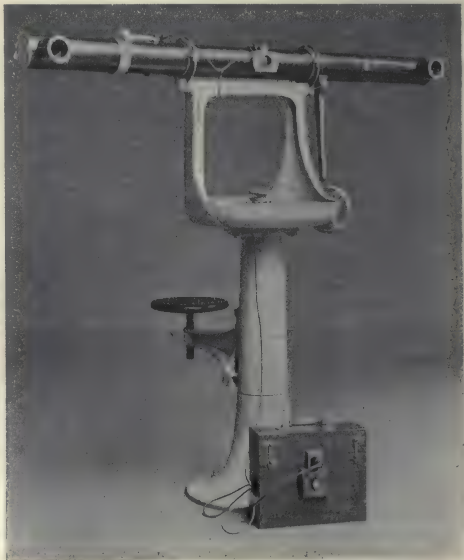

Fig. 3.—Barr and Stroud range-finder on fortress mounting.

This instrument, in favourable circumstances of weather, will measure ranges in a few seconds of time with an accuracy of something like 3 yards at 1000 yards, 30 at 3000, 120 at 6000, and so on. Prof. Barr, of the University of Glasgow, and the lecturer devised the instrument in its main features in 1888; it took, however, a period of five years to make a satisfactory naval instrument, and for the past seven years the improvement of the optical and mechanical details has been going on.[1]

Fig. 3 shows the same instrument mounted for fortress observation.

It is claimed for these instruments that they offer a solution —of course not necessarily the only or the best—of the problem of range-finding in all cases where want of portability is not a drawback.

*B. and S. Field Range-finder.*—Fig. 4 shows a smaller instrument of the same type with a base of 3 feet, which weighs 12 lbs. One of these instruments has been used by Major Guinness in South Africa since the beginning of February, and that officer reports that after carrying the instrument on his ammunition wagon over all sorts of ground for six months it was in no way damaged or deranged. The figure shows how the range-finder can be used for taking a distance with practically no exposure of the man.

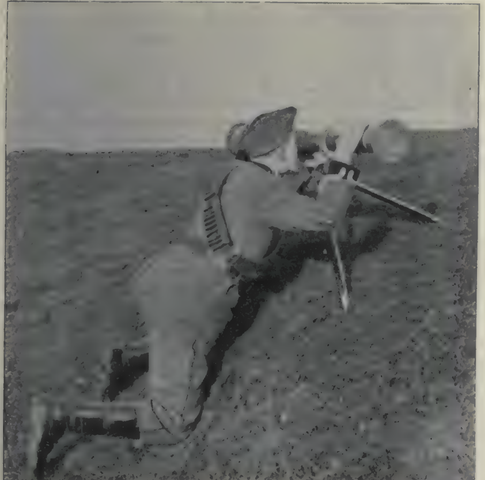

Fig. 4.—Barr and Stroud field range-finder.

The lecturer concluded by describing and exhibiting the electrical telegraph for naval use which Prof. Barr and he had devised at the request of the Admiralty, so as to enable the captain of the ship in the conning tower to receive from the range-taker continuous records of the enemy's distance and to transmit the same and also orders to the guns. The importance of trustworthy means for transmitting orders and other communications from one station to another on a warship is now fully realised. Thus, for example, it is reported that in the opinion of Admirals Fournier and de Beaumont and the officer in command, the loss of the French torpedo-boat destroyer *Framee*, which occurred about a month ago, was due to the fact that the apparatus on board the vessel for the transmission of orders was inadequate. The need for continuous and almost instantaneous transmission of ranges to the gunners will be obvious when it is remembered that in naval engagements the range is continually and rapidly altering.

The lecturer concluded by expressing his thanks to Mr. J. J. Hicks, of London, Mr. Steward, of London, and Messrs. Zeiss, of Jena, for the loan of range-finders to illustrate the lecture.

## MECHANICS AT THE BRITISH ASSOCIATION.

Although no very striking paper was presented to the section at this meeting, still several papers of value and of considerable interest were dealt with.

In the committee of the section two very important pieces of work were carried out. The committee on small screw gauges, which has now been at work for some years, presented an interim report in which the difficulties the committee had met with in obtaining standard gauges were very fully discussed, and an account of some experiments on different forms of threads, made by Mr. T. M. Gorham and Mr. W. A. Price in the laboratory of Prof. Hudson Beare at University College, London, were described. The committee stated in their report that they have now every hope of bringing their inquiry to a successful conclusion, and the committee was therefore reappointed and a grant was secured for the necessary expense of completing the work.

A committee was also appointed at Bradford to deal with the question of the resistance of road vehicles to traction. Prof. Hele Shaw read a short paper before the section, drawing attention to the need of modern experiments on the nature of the resistances encountered by vehicles on the common road. He pointed out how the growth of the cycle and motor car industry made information upon this point a matter of the greatest importance.

There is no doubt that we are on the eve of a very considerable increase in mechanical propulsion on common roads, and at present designers of such vehicles have to rely largely upon old experiments with solid steel tyres, and carried out on roads very different indeed from the modern roads. The powerful auto cars which can now be obtained make it comparatively an easy matter to determine the tractive power necessary to move a vehicle with any load upon any type of road, and no doubt the work of the committee will largely consist—after a suitable dynamometer and speed indicator have been arranged for—in carrying out exhaustive experiments with different types of vehicles and different types of tyres on all the various classes of roads now in use.

A grant of money was secured from the Association for the purposes of this committee, and we have every hope that when the committee submits its report it will justify its appointment.

In the work of the section papers by local engineers bulked largely. Perhaps the two most interesting and valuable were a paper by Mr. J. Watson, the Waterworks engineer at Bradford, in which the new Nidd Valley Waterworks were described, and the paper by Mr. J. MacTaggart, the Superintendent of the Cleansing Department of the City of Bradford, entitled "The Disposal of House Refuse in Bradford."

In Mr. Watson's paper a short historical summary of the various schemes for supplying Bradford with water was given, followed by a very exhaustive and complete account of the Nidd Valley scheme. This scheme, now rapidly approaching completion, is one which will cost the City of Bradford nearly 1,500,000*l.* and will afford a supply of about twenty million gallons of water per day, and in addition will provide a large compensation reservoir (Gouthwaite) for the land-owners along the Nidd Valley.

It is essential for such a city as Bradford, where the chief industry is that of the woollen trade, that the water shall be very soft, and, of course, this led to some difficulty in finding a suitable collecting ground for the city supply.

The section had the opportunity of visiting, under the guidance of Mr. Watson, portions of the works on the Saturday of the meeting.

In Mr. MacTaggart's paper very valuable information was given as to the most modern methods in a big manufacturing city for the disposal of the daily city refuse. So successful have the various arrangements been, mostly due to the author, that it is hoped in time the destruction of the whole of the refuse of the city will be carried out, not only without creating any nuisance, but without any cost to the ratepayers. The refuse is chiefly dealt with by destructors, and the great merit of the Bradford system is in the utilisation of the clinker produced in the destructor furnaces for various useful purposes, the power to work the machinery required for these purposes, and the lighting of the works all being obtained from the steam generated by the surplus heat of the destructors. A large number of specimens were shown to the section of concrete paving-slabs, bricks and encaustic tiles manufactured from the clinker, and some interesting figures as to the strength of these materials were also given.

---

[1] Readers unacquainted with the instrument are referred for details of its construction to *Transactions* of Inst. of Mech. Eng. (1896), or *Engineering*, 1896 Part i. p. 233, &c.

Another paper by a Yorkshire engineer, Mr. E. K. Clark, dealt with the subject of the shop buildings in large engineering works. The author had collected a large amount of statistics and figures, both as to the method of construction now generally adopted—viz., the shops all on one level—and as to the materials commonly used in their construction, and the paper will form a very valuable reference for any engineer engaged either in laying out new engineering workshops, or in reconstructing old buildings.

Mr. Glass contributed a lengthy paper dealing with the coal and iron ore fields of Shansi and Honan, and railway construction in China. The author was engaged in 1898 by a syndicate to proceed to China, and to examine and make a complete report on the coal and iron-ore fields of these two important provinces of China, and also to make surveys for the railways which it would be necessary to construct in order to utilise these deposits.

An interesting description was given of the general features of the country, illustrated by some beautiful lantern slides from photographs taken by the author, and also a very complete account of the Chinese method of working these mineral deposits. The author stated that it was somewhat difficult to arrive at very exact estimates of the quantity of coal available in these great fields, but it is believed there are more than 33,000 square miles of coal-fields in Shansi alone, and that the present output of Great Britain, which is more than 200 million tons a year, could be maintained from the anthracite coal-fields of Eastern Shansi alone for a period of 3000 years.

Samples of the coal have been analysed and show that it is a good steam coal.

Similar favourable accounts were given in regard to the iron ore deposits, and the author computed that it would be possible to produce a ton of pig-iron from these ores at the very low cost of 12s. 1½d. per ton, assuming labour to be at the same rate as it is now at Middlesbrough in England. The lowest price at which the pig-iron was being sold at the foundries visited by the author was a little over 20s. per ton.

The extraordinary richness of these mineral deposits and the enormous area awaiting development show how pressing the problem of reorganising peacefully the internal government of China is for the civilised world.

On the day devoted to electrical engineering, two short communications were read by Sir Wm. Preece and Mr. F. J. Behr, dealing with the proposed Monorail High Speed Electric Line between Manchester and Liverpool.

It will be remembered this scheme came before Parliament last session and was rejected, largely owing to the strenuous opposition of the existing railways.

The interesting feature in these papers was the account given of the brakes and signals which it is proposed to adopt, which must be an important matter on a line where it is proposed to run the trains at frequent intervals, and at such an excessively high speed as 110 miles per hour. Perhaps if the promoters had been content to reduce the proposed speed somewhat at the beginning, their scheme might have been more favourably considered.

A valuable paper dealt with on this day was one on the measurement of the tractive force, resistance and acceleration of trains, by Mr. A. Mallock. The author described the apparatus which he used for the purpose, and gave an account of some experiments which he has recently carried out on these important questions. He concluded from his results that pendulum observations combined with a record of speed and power offer a simple and effective means of determining the resistance to and efficiency of electric or other kinds of motor vehicles.

On this day also, a communication from Mr. W. T. E. Binnie, a son of the president, was read, describing a new form of self-registering rain-gauge which he has invented. The accuracy of the gauge depends on the fact that all drops falling from a tube are of constant size, provided that the tube is either very small so that the water passing down the interior chokes the bore, or that some special device is provided to spread out the water so as to wet the entire circumference of the tube. If, therefore, the weight of each drop were ascertained, it is clear that a measure of the amount of water passing down the tube would be obtained by counting the number of drops, and the electrical appliances are concerned with this part of the work.

An instrument made on this principle has been in operation for some time, and the records obtained from it in a period of five months give a total excess of 1·6 per cent. over the register of an ordinary rain-gauge.

Mr. W. Dawson contributed a paper descriptive of the Demerbe system of tramway construction, a system which has been tried on the Bradford Corporation tramways and found very successful in the reduction of the cost of permanent way repairs. In the Demerbe system the rail consists of a hollow trough and the fish plate is placed inside under the ends of the rails and exactly fits its contour, the fish-plate being forced into close contact with the under side of the rail by driving in two cotters. The rail, when laid in position, is completely filled, by means of specially-designed tools, with concrete. The tie bars are flat and very simply arranged, and the gauging of the rails can, therefore, be done rapidly with almost mathematical exactitude.

The system certainly seems to have considerable merits compared to the girder system of tram rails.

Two other instruments described in short communications were a combination integrating wattmeter and maximum demand indicator, the invention of Mr. J. H. Barker and Prof. Ewing, and a new form of calorimeter for measuring the wetness of steam, designed by Prof. Goodman.

The former instrument is designed to measure two quantities, the total amount of electricity used by a consumer and the maximum number of lamps or their equivalent ever lighted at one time. By this means it is possible to grade the charges for electric energy, and it enables the consumer to be charged at a lower rate for current he may use over and above the units which would have been used had the largest number of lamps in his installation burnt for one hour every day during the whole period the current was in use.

Prof. Goodman's instrument is intended to get over some of the more serious difficulties in measuring the wetness of steam supplied by any boiler. He discards entirely the wire-drawing system, and determines the wetness by condensing a known weight of the mixed steam and water in a known weight of cold water, and measuring the rise of temperature.

Prof. Beaumont, of Leeds, in a most interesting paper described the photographic method of preparing textile designs due to Szczepanik, a number of designs being shown which had been produced by this process.

In continuation of a paper which was read before the Association at Liverpool in 1896, Mr. A. T. Walmisley gave further information as to the use of expanded metal in concrete work, and gave particulars of a number of important tests which have been carried out to determine the increase of strength and the adhesion between the concrete and the metal.

The attendance at the sectional meetings was very good, and the president, Sir Alexander Binnie, may be congratulated on a successful and useful meeting.

## *BOTANY AT THE BRITISH ASSOCIATION.*

IN the absence of Prof. Vines the presidential address was read by Dr. D. H. Scott. On the motion of Prof. Bayley Balfour, supported by Prof. Marshall Ward, Prof. Bower and other speakers, it was unanimously agreed to ask the Recorder of the Section to convey to Prof. Vines the sincere regret of the Botanists that he was prevented by illness from presiding over their meeting.

The customary semi-popular lecture was this year delivered by Prof. Percy Groom, who chose for his subject "Plant-form in relation to nutrition."

On Monday, September 10, the Section of Geology joined Section K in a discussion on the conditions under which the plants of the Coal Period grew. The discussion was opened by Mr. Kidston (Stirling), who gave a general account of the flora of the Coal-measures, illustrated by a series of excellent photographs of the various types of Upper Carboniferous plants. Mr. Seward dealt with the botanical evidence bearing on the climatic and other physical conditions under which coal was formed. On the geological side the discussion was opened by Mr. Strahan and Mr. Marr. Dr. Horace Brown discussed the question of the possible richness in $CO_2$ of the coal period atmosphere, and gave an account of some of his recent experiments with plants grown in an atmosphere containing twice or thrice the present amount of carbonic acid gas. Dr. Scott, Dr. Blackman, and Prof. Hartog also took part in the discussion from the botanical standpoint.

### General.

Prof. Bower, F.R.S., gave an account, illustrated by several excellent photographs, of sand-binding plant as seen in the dunes on the Scotch coast in the neighbourhood of North Berwick.

British sylviculture, by Samuel Margerison. In this communication attention was called to the large importation of foreign timber, and the urgent need of Government aid in the production of British timber. The author spoke of the existence of much land in this country at present unproductive, or only slightly productive, which is suitable for giving a native supply of timber. He compared the results of Continental and British sylviculture, and pointed out that in Britain the natural conditions are not less favourable, but the management is generally inferior. The author urged the importance of encouraging forestry schools which should afford opportunities for detailed research and teaching, with equipment, scientific and practical, worthy of the subject.

The great smoke-cloud of the North of England and its influence on plants, by Albert Wilson. The author spoke of the extent of the great smoke-producing district of the North of England and the miserable condition of the vegetation in some parts of the area. Among the various points dealt with in the paper, the following may be mentioned, the long distance reached by the smoke of large towns; the discoloration of rain-water ("black rain"); the effect of smoke on mosses and hepatics as compared with that on higher plants; the threatened extinction of *Ulota* and *Orthotricha;* the influence of smoke on sunshine and air-temperature in calm summer weather and in anti-cyclonic weather during autumn or winter.

Embryonic tissues, by Prof. Marshall Ward, F.R.S. The author urged the advisability of improving the current terminology with regard to the nature and growth of the tissues termed embryonic. Sachs termed all the tissues of the growing-points, cambium, pericycle, &c., embryonic tissues. Prof. Ward would restrict the term *embryonic tissue* to that of the embryo alone before the desmogen strands are developed, the other tissues being designated *derived* or *secondary tissues.* The tissues of the growing-points are derived from embryonic tissue, and differ from it in that, instead of being capable of developing all or any part of the plant, they are more or less restricted to the power of developing shoots, leaves, &c., or only roots. The proposed classification would apply equally to the lower organisms; some of the Algæ and Schizomycetes appear to be always in the embryonic stage. Prof. Ward also urged the desirability of distinguishing between the *assimilatory* growth of true embryonic tissues and the *vacuolar growth* of the derived tissues.

### Physiology.

Dr. F. F. Blackman and Miss Matthaei communicated the results of their recent work on the effect of the closure of stomata on assimilation; Dr. Blackman also gave an account of his investigations on the so-called optimum strength of $CO_2$ for assimilation.

Formation of starch from glycollic aldehyde by green plants, by Henry Jackson. Glycollic aldehyde has lately been isolated in a crystalline state, and more recently it has been shown by the author that this substance, under the influence of dilute alkalis, very quickly condenses to two synthetic hexoses. Leaves of *Tropaeolum* and clover, which had been depleted of their starch by growing in the dark, were floated in a three per cent. aqueous solution of diose, control experiments being made with cane-sugar, glycerine and distilled water, the whole series being kept in the dark for six days. They were then tested by Sach's method; those floating in pure water were quite starchless, those in glycerine almost so, but those growing in diose had accumulated starch in the tissues, though not to the same extent as those placed in cane-sugar.

On the effect of salts on the $CO_2$ assimilation of *Ulva latissima,* L., by E. A. Newell Arber. It was found that an inhibition of the power of $CO_2$ assimilation could be caused by the presence or absence of certain salts in the medium. *Ulva* was obtained free from starch and exposed to light in various media. In distilled water only a very small amount of starch was formed, while in tap-water containing traces of nutrient salts the inhibition was only partial. The presence of NaCl in the medium was found to be essential in order to obtain the maximum of $CO_2$ assimilation. A total or almost total absence of NaCl caused a very marked inhibition, and no other salt could be found to replace NaCl in regard to $CO_2$ assimilation. The absence from sea-water of any one of the following salts, $MgCl_2$, $MgSO_4$, $CaSO_4$, or KCl, did not inhibit the assimilation. The presence of a nitrate in appreciable quantity in the medium caused an inhibition.

The sea-weed *Ulva latissima* and its relation to the pollution of sea-water by sewage, by Prof. Letts and J. Hawthorn. For a number of years past a very serious nuisance has arisen from the sloblands of the upper reaches of Belfast Lough during the summer months, the stench at low-tide being quite overpowering, and the air heavily charged with sulphuretted hydrogen.

The nuisance is caused by deposits of the green sea-weed, *Ulva latissima,* which in the two localities mentioned grows in abundance, and during high winds or gales is washed ashore. In Belfast Lough the quantity thus deposited is enormous. Once deposited, these layers of sea-weed often remain more or less stationary for months in the shallow bays or pools of the neighbourhood, and in warm weather rapid putrefaction occurs, and a perfectly intolerable stench arises, which is perceptible over a wide area and seriously affects, not only the comfort of the inhabitants of the district, but also the value of their property.

The evidence which the authors have collected tends to the conclusion that the occurrence of *Ulva latissima* in quantity in a given locality is an indication of sewage contamination, and there can be no doubt as to the power which the weed possesses of absorbing nitrogen compounds from polluted sea-water. While thus acting as scavenger it may itself give rise to a very extensive nuisance.

Further investigations on the intumescences of *Hibiscus vitifolius,* L., by Elizabeth Dale. In a previous paper (*Proc. Phil. Soc. Camb.* vol. x. 1900, p. 192) the author gave the results of some experiments, which pointed to the conclusion that the conditions determining the formation of the outgrowths were moisture, warmth and light. More recent work has given the following results: (1) In a moist atmosphere, bright sunlight and a high temperature, large numbers of intumescences were formed in two or three days; (2) outgrowths were produced under red, yellow and white-washed glass, but not under blue or green glass; (3) the distribution of outgrowths is dependent upon that of the stomata; (4) the checking of transpiration in a damp atmosphere is one cause of the development of the outgrowths, but this in itself is insufficient. There is further evidence that an altered course of metabolism is also involved.

### Anatomy, Palæobotany, &c.

On a fourth type of transition from stem to root-structure occurring in certain monocotyledonous seedlings, by Ethel Sargant. Van Tieghem dercribed three types of transition from a stem to a root-structure (*Traité de Botanique,* 1891, p. 782). Miss Sargant found a fourth type in certain monocotyledonous seedlings. The best example is *Anemarrhena asphodeloides,* but there are very clear traces of the same structure in some allied genera. In *Anemarrhena asphodeloides* there are two bundles in the cotyledon which pass downwards through the hypocotyl into the primary root. During the transition each phloem group divides into two. Each xylem group branches in three directions. It sends a group of protoxylem elements to divide its own two phloëm groups from each other. Two lateral protoxylem groups are also formed from the xylem of each bundle in the space dividing the bundles from each other. The four lateral protoxylem groups thus formed are reduced to two by the fusion of adjacent groups in pairs. In the end, there are four phloem groups and four protoxylem groups in the root-stele.

On the presence of seed-like organs in certain Palæozoic lycopods, by Dr. D. H. Scott, F.R.S. Specimens discovered by Messrs. Wild and Lomax in the Lower Coal-measures of Lancashire prove that the seed-like bodies described by Williamson under the name of *Cardiocarpon anomalum* were borne on strobili, agreeing with *Lepidostrobus.* Each megasporangium, which was seated on the upper surface of the sporophyll, became enclosed, when mature, in an integument springing from the tissue of the sporophyll-pedicel. The integument closed in over the top of the sporangium, leaving only a narrow crevice or micropyle, which differed in its elongated, slit-like form from the more or less tubular micropyle of an ordinary seed. Within the megasporangium four megaspores were produced, one of which occupied almost the whole of the sporangial cavity, while the other three remained small, and were evidently abortive. The integumented megasporangium, containing the single functional megaspore or embryo-sac, became detached, together with the remains of its sporophyll, from the cone. It appears to have been indehiscent, and presents close analogies with a true seed. In a male strobilus, probably of the same species as the specimens above described, the microsporangia were found to be provided with integuments, resembling those of the megasporangia, but more widely open.

It is proposed to give the generic name *Lepidocarpon* to this Lepidostroboid fructification.

The primary structure of certain Palæozoic stems referred to *Araucarioxylon*, by D. H. Scott, F.R.S. The Palæozoic forms of *Araucarioxylon* have been shown to belong in most cases to the stems of the extinct Gymnospermous order Cordaiteæ, which was in some respects intermediate between Cycadales and Coniferæ. The Cordaitean stems hitherto investigated resemble Coniferæ in the development of their wood, for the spiral first-formed tracheides are found in contact with the pith, the whole of the wood, primary as well as secondary, having thus been developed in centrifugal order. The specimens of Lower Carboniferous age now illustrated are peculiar in possessing distinct strands of primary wood in the pith. In one, *Araucarioxylon fasciculare*, sp. nov., the pith is small, but the primary strands of xylem are of large size, attaining their maximum diameter when about to pass out towards a leaf. Their structure is mesarch, and they closely resemble the corresponding strands in *Lyginodendron Oldhamium*. The secondary wood has narrow medullary rays, and resembles that of an araucarian Conifer. The other species is identical with *Araucarioxylon antiquum* of Witham. The interest of the two species (described from specimens in Mr. Kidston's collection) consists in their affording a link between certain of the Cycadofilices and the Cordaiteæ.

On the structure and affinities of *Dipteris conjugata*, with notes on the geological history of the Dipteridinæ, by A. C. Seward, F.R.S., and Elizabeth Dale. The genus *Dipteris* is represented by four recent species: *D. conjugata*, Reinw. [= *Polypodium* (*Dipteris*) *Horsfieldii*, R. Br.], *D. Wallichii*, R. Br., *D. Lobbiana*, Hk., and *D. quinquefurcata*, Baker. Among Mesozoic ferns the genera *Protorhipis*, *Dictyophyllum* and *Camptopteris* afford examples of extinct types closely allied to *Dipteris*, and widely spread geographically during the Jurassic epoch.

The sporangial characters of *Dipteris* do not conform precisely to those typical of the Polypodiaceæ, and the anatomical features afford additional evidence in favour of placing *Dipteris* in a special subdivision of the leptosporangiate ferns.

The paper dealt with the structure of the stem, which possesses a single annular stele, the roots, leaves and sporangia of *Dipteris conjugata*, the comparison of the anatomical features with those of the Cyatheaceæ and other ferns, and concluded with an account of the geological and geographical range of such fossil ferns as may reasonably be placed in the family Dipteridinæ.

On the structure of the stem of *Angiopteris evecta*, Hoffm., by R. F. Shove, Girton College, Cambridge. This paper dealt with the anatomy of the stem and roots of a plant of *Angiopteris evecta* from Ceylon.

The steles of the stem are both mesarch and endarch in structure, but the protoxylem groups occupy for the most part a peripheral position. The earliest protoxylem appears along the inner edge of the steles, while the protophloem arises on the outer edge of each stele as a discontinuous arc of small and rather thick-walled elements. This arc of protophloem is never completed round the stele, but the next stage in the development of the tissues after the appearance of the protoxylem is the differentiation of large sieve-tubes external to the protophloem.

The conducting tissues of Bryophytes, by A. G. Tansley. The most important part of our present knowledge of these tissues is due to Haberlandt, who, in the Polytrichaceæ, distinguished a *hadrom* (*hydrom*) or water-conducting system from a *leptom* system, conducting plastic, especially nitrogenous substances.

In the present investigation the lignified strand of prosenchyma in the thallus of certain Liverworts was shown to be a hydrom strand, and its development was considered to be correlated to some extent with the localisation of the absorptive region of the thallus.

The rhizome of four species of *Polytrichum* was investigated, and was found to possess the distribution of tissues characteristic of the root of a vascular plant. The transition to the structure of the aërial stem was followed, and some new points in the structure and course of the leaf-traces were observed; new light was thrown also on the constitution of the Polytrichaceous stele, which is thought to consist of two regions distinct in function and by descent. An attempt was made to trace out the course of evolution of these conducting tissues in the Bryophytic series.

The origin of modern Cycads, by W. C. Worsdell. The author's conclusion is that the Cycads are descended directly from some cycado-filicinean type possessing the structure exhibited especially by such forms as the Medulloseæ and Lyginodendreæ, the chief point being that the *collaterally*-constructed one or more vascular cylinders of modern cycads have been derived from one or more *concentrically*-constructed cylinders of some cycado-filicinean form. Those characters in the modern plants which approximate most nearly to the primitive ancestral type are found in those parts of the plant where they would most naturally be expected, viz.:—The *axial* organs: the *primary node* or transitional region between stem and root, and the *flowering axis*; the *foliar* organs: the *cotyledon*, the *sporophyll*, and the *integument* of the sporangium. The author discussed the evidence derived from an anatomical study of recent cycads, and dealt with certain fossil types which he regarded as supporting his conclusions.

### CYTOLOGY, &C.

On the osmotic properties and their causes in the living plant and animal cell, by Prof. Overton. A very great number of experiments on the permeability or the living protoplasm of plant and animal cells has led to the conclusion that the general osmotic properties of the cell depend on a phenomenon of *elective solubility*, certain layers of the protoplasm being impregnated with a mixture of lecithin and cholesterin. All substances that are soluble in this mixture, and they include by far the greater number of organic compounds, being able to penetrate into the living cell. The rapidity of the passage of different compounds into the cell depends on their relative solubility in water and in a mixture of cholesterin and lecithin. A knowledge of the osmotic properties of the living protoplasm throws much light on the action of many poisons and other drugs.

Demonstration of the structure and attachment of the flagellum in *Euglena viridis*, by Harold Wager. The flagellum of *Euglena viridis* possesses a bifurcate base, which is attached to the wall of the excretory reservoir at the anterior end of the body (*Journ.* Linn. Soc. Zool. vol. xxvii. p. 463). As it passes to the exterior through the gullet, an enlargement occurs in the region of the eye-spot. This structure can be seen in very favourable cases in the living condition, but usually only after the action of reagents. The best reagents for this purpose are either a 1 per cent. solution of osmic acid or a 2 per cent. solution of bichromate of potash with a 1 per cent. solution of osmic acid. The structure may be obscured by small grains of paramylon, which sometimes accumulate at the anterior end of the body.

The behaviour of the nucleolus during karyokinesis in the root-apex of Phaseolus, by Harold Wager. From a study of the changes undergone by the nucleolus during karyokinesis in cells of the root-apex of *Phaseolus multiflorus*, the following chief results have been obtained.

(1) The nucleolus is the most conspicuous object in the nucleus of the young meristematic cells. The nuclear network forms a delicate peripheral layer only in the resting nucleus. (2) The nucleolus stains deeply in hæmatoxylin, the nuclear network slightly; in safranin and gentian violet the nucleolus stains red, the nuclear network light blue. (3) In the resting condition of the nucleus the nucleolus is suspended to the nuclear network by delicate filaments. (4) The nucleolus often shows a vacuolar structure. (5) In the process of nuclear division the nucleolus first of all becomes irregular in shape, and the nucleolar substance appears to pass, by means of the connecting strands, into the nuclear network, which thereby becomes more prominent. (6) As the chromosomes are formed the nucleolus disappears, but a portion of the nucleolus is often visible in the equatorial plate. (7) The chromatic substance of the chromosomes appears to be derived almost entirely from the nucleolus. (8) As the daughter-nuclei are being formed the chromatic substance of the chromosomes runs together into small spheres, which ultimately fuse to form the single large nucleolus.

On double fertilisation in a dicotyledon, *Caltha palustris*, by Ethel N. Thomas. The polar nuclei of this plant unite before fertilisation, but that there is no absolutely fixed period is shown by the very different appearance of sacs in which polar fusion is taking place. The male generative nuclei, when first set free in the embryo-sac, are extremely small and heavily stained. Their chromatic substance is so densely aggregated as to render the spermatozoid to all appearance homogeneous. Of the two spermatozoids one passes to the middle of the sac and there *fertilises the definitive nucleus*; the other fertilises the nucleus of the oosphere. By the time the male generative nucleus or spermatozoid has reached the definitive nucleus, it has enlarged immensely, and shows a light spongy structure with scattered chromatin granules. The other spermatozoid increases very little in size, and always remains dark and dense.

When the spermatozoids leave the pollen-tube they are somewhat short and thick, and only slightly curved, but when the one has approached the definitive nucleus, it has the typical vermiform shape, with one or several coils.

### THALLOPHYTA.

Germination of the zoospore in Laminariaceæ, by J. Lloyd Williams. The zoospore comes to rest and becomes spherical. The single chloroplast divides in two. A tube is produced, the spore-contents pass into it. At the end of the tube a swelling is formed, into which the contents migrate and are shut off from the empty spore-case and tube by a wall. This has been wrongly described by Areschoug in the case of *Dictyosiphon* as an instance of sexual fusion. In the enlargement, the chloroplasts multiply, and additional eyespots appear on several, which, however, disappear after a few days. The newly-separated cell now divides, and forms a branched protonema-like structure.

Notes on *Dictyota*, by J. Lloyd Williams. The factors concerned in the production of the fortnightly crops of sexual cells were discussed. Experiments on the liberation of antherozoids show the importance of bright light and cool temperature. *Dictyota* is particularly responsive to changes in the environment.

The nuclear changes in the unfertilised eggs are peculiar. The chromosomes are differentiated, a very irregular multipolar spindle is formed; this separates into a number of nuclei of various sizes, in which at first the chromosomes are scattered. These soon disappear, the nucleoli are formed, and the nuclei appear in the resting condition.

The *Azygospores* of *Entomophthora gloeospora*, by Prof. Vuillemin (Nancy) (communicated by Prof. Hartog). The genus *Entomophthora*, as seen in the two species *E. Delpiniana* and *E. gloeospora*, shows an intermediate condition between *Basidiobolus*, with its uninucleated segments, and *Empusa*, with its continuous hyphæ with scattered nuclei. The resting-spores of *Entomophthora* may be terminal, lateral or intercalary. The youngest spores contain a single nucleus, which undergoes a series of four successive binary divisions until there are sixteen; there may, however, be irregularities as regards the number of spores. In the next stage the nuclei approach so as to form eight pairs, and the two nuclei of each pair then fuse; this fusion is repeated until there are only two left. These last two may then fuse at once, so as to leave the now maturing azygospore with a single nucleus, or they may remain apart. This manner of development is interpreted as a case of true apogamy, and regarded as corresponding to the sexual process in *Basidiobolus*.

Fungi found in Ceylon growing upon scale-insects (*Coccidae* and *Aleurodidae*), by J. Parkin. Fungi associated with scale-insects have till recently been little studied. A few species have been mentioned from time to time as growing upon scales of dead coccids, but, till within the last few years, hardly any attention has been called to their probable parasitic character, or to the possibility of their being employed to check the ravages of scale-pests. Webber in 1897 pointed out for the first time the parasitic habit of certain species—five in all—of *Aschersonia* on scale-insects infesting the orange and other plants in Florida. Zimmermann (Java) in the following year gave a preliminary account of a fungus (*Cephalosporium*) attacking the green bug (*Lecanium viride*), so harmful to the coffee, and described how it may be artificially cultivated for infecting experiments.

The various kinds dealt with were referred to the following genera:—*Nectria, Torrubiella, Aschersonia, Cephalosporium, Verticillium, Microcera, Campsotrichum* (?).

Mr. Parkin drew attention to the wide distribution, especially in and near the tropics, of fungi infecting scale-insects, and referred to them as the true cause of death of the insects. The paper was illustrated by a series of carefully-prepared specimens and drawings.

On the life-history of *Acrospeira mirabilis* (Berk. and Br.), by R. H. Biffen. Loose brown masses of the spores of this fungus are occasionally found in Spanish chestnuts. These spores are developed from the apices of hyphæ coiled into a spiral of, at the most, two turns, which becomes septate into three cells; the cell next below the apical one swells and becomes thick-walled, thus forming a chlamydospore. The coiled hypha may also develop into a spiral resembling the ascogonium of *Eurotium*, which, after investment by branches arising from its apex, breaks down into chlamydospores. In this way bodies very suggestive of the spore-masses of some of the Ustilagineæ are formed. Endoconidia are found in old cultures. Some evidence has also been obtained for the existence of an ascigerous stage.

On the structure of the root-nodules of *Alnus glutinosa*, by T. W. Woodhead. The nodules are traversed by a central strand of short, thick-walled fibres, with transverse pits in the walls. Surrounding this are 4–5 layers of cubical cells, rich in protoplasm, followed by a small-celled bulky cortex. On the outside of this is a phellogen, which produces a layer of cork several cells deep. The cortical cells are largely occupied by the organism which produces the nodule.

The organism is usually present as a globular sporangium at the end of a short hypha. Towards the base of the nodule are strands of cells occupied by disorganised contents indicating a previous tract of growth of the organism: this is succeeded by groups of cells filled with the organism in various stages. Towards the apex, and immediately behind the growing-point, the cells containing the sporangia are immediately followed by cells filled with fine hyphal filaments, which may be seen to penetrate the walls of the young adjacent cells.

A Gymnosporangium from China, by Prof. F. E. Weiss. This fungus was first observed by Dr. A. G. Parrott in the spring of 1899 in Lao-ho-kou, in North Central China. Its spore masses made their appearance in April after a few days' continuous rain on the branches of *Juniperus chinensis* in the form of bright yellow, gelatinous masses. The teleutospores are of the usual type, two-celled, tapering towards both ends and somewhat rounded at the apex. They possess eight germ-pores. What is in all probability the *Roestelia* stage of this fungus was observed during the summer on the leaves of the pear, *Pyrus sinensis*, Ldl. A tree of this species growing in proximity to the infected junipers was attacked by a fungus of the *Roestelia* type, producing typical æcidiospores.

In the appearance of its teleutospore masses this fungus appears most nearly related to *Gymnosporangium Sabinae* (Dicks), a widely distributed form occurring in Europe and in America, and to *Gymnosporangium Cunninghamianum* (Barclay), a Himalayan form, both of which have their *Roestelia* stage on a pear.

The biology and cytology of Pythium, by Prof. Trow. The species described by the author was cultivated from conidia and oospores found in rotten cress seedlings. The study of pure cultures led to the following among other conclusions:—(1) No zoospores are produced under any circumstances. (2) The species is new and ranks as the most highly developed of the genus. (3) The fertilisation-tube penetrates the wall of the oogonium at a spot prepared for it, passes through the periplasm and penetrates deeply into the egg. One male nucleus passes down the tube and enters the egg. The oosphere clothes itself with a delicate wall and increases in size. (4) The fusion of the male and female nuclei is delayed until a thick oospore wall has been developed. (5) The nuclei multiply by indirect division in the mycelium and sexual organs. The only nuclear fusion is that of the male and female nuclei in fertilisation.

Observations on Pythium, by M. Poirault and E. J. Butler. The authors examined seven species, two of which were undescribed forms. In two species, *Pythium gracile* and *P. intermedium*, sexual organs were observed for the first time. Klebs' results on the dependence of spore-formation in *Saprolegnia* on external conditions were carried a step further, it being shown that a given spore could be induced to develop zoospores or vegetative hyphæ on appropriate treatment. The authors conclude that *Pythium* represents a stage in the colonisation of the land, by saprolegniaceous ancestors resembling *Aphanomyces*. It is closely linked to the *Peronosporaceae* through *Pythium intermedium*, which possesses chains of gonidia, suckers, and a thick-walled mycelium.

Observations on some Chytridineæ, by M. Poirault and E. J. Butler. Four undescribed forms occur parasitic on *Pythium*. Their life-history has been worked out by the authors. *Chytridium gregarium* was found on the eggs of the rotifer *Metopidia Lepadella*; the unknown resting-spores were discovered. Observations were made on *Olpidiopsis Saprolegniae*. The infection takes place in the zoospore-stage of *Saprolegnia*, and is often multiple. Penetration takes place by a fine tube, through which the protoplasm of the parasitic zoospore enters the host, leaving behind an empty capsule. A. C. S.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

OXFORD.—The following lectures are announced for the present term: Prof. R. B. Clifton, Acoustics; J. Walker, Double refraction; R. E. Baynes, Elementary mechanics of solids and fluids, and Mathematical theory of heat; Prof. W. Odling, Organic chemistry, metallic bodies; W. W. Fisher, Inorganic chemistry (preliminary course); J. Watts, Organic chemistry (honours course); V. H. Veley, Physical chemistry; J. E. Marsh, Stereochemistry; A. G. Vernon-Harcourt, The subjects of the preliminary examination (chemistry); P. Elford, Mendeléeff's periodic system. Introduction and group I; P. Elford, Chemists and their work; A. F. Walden, Origin, meaning and use of chemical symbols, formulæ and equations (elementary course); Prof. W. J. Sollas, Physical geography; Prof. W. J. Sollas, Jurassic fossils; Prof. H. A. Miers, Elementary crystallography; H. L. Bowman, The metallic minerals; Prof. W. F. R. Weldon, General course of morphology (Coelentera); J. W. Jenkinson, Elementary morphology; E. S. Goodrich, Morphology of fishes; R. W. T. Günther, Polyzoa and brachiopoda; J. B. Thompson, Morphology of the ichthyopsida; J. B. Thompson, Ichthyopsidan palæontology; Prof. F. Gotch, General course of physiology, Part I. chemical processes; Prof. F. Gotch, Advanced course on muscle; J. S. Haldane, Subjects of the final honour school (physiology); G. Mann, Histology: G. J. Burch, Physiological physics; W. Ramsden, Introduction to physiological chemistry; G. Mann, Practical histology; W. Ramsden, Elementary physiological chemistry; Prof. S. H. Vines, Short elementary course (revision) with practical work; Prof. E. B. Tylor, Development of language, writing, arithmetic; H. J. Mackinder, The historical geography of the British Islands; H. J. Mackinder, The development of geographical ideas; H. N. Dickson, The atmospheric circulation; A. J. Herbertson, The geographic cycle; Sir J. Burdon-Sanderson, General pathology; Prof. A. Thomson, Anatomy of the nervous system; Prof. H. H. Turner, Elementary mathematical astronomy; Prof. A. E. H. Love, Gravitational attraction, and theory of the potential; and the theory of sound; Prof. E. B. Elliott, Theory of numbers; and substitutions and resolvents; Rev. F. J. Jervis-Smith, Dynamo and motor machinery and electrical testing; G. F. Stout, Child psychology; and the psychological development of the categories of subject, cause and end.

The electors to the newly instituted Wykeham Professorship of Physics will proceed to an election in November. Candidates are requested to send in their applications by October 24. The electoral body consists of the following:—The President of the Royal Society, Sir George Stokes, Prof. Esson, Prof. Odling, Mr. Hayes.

The Rev. E. C. Spicer, of New College, has been elected to the University Scholarship recently instituted in connection with the new School of Geography.

CAMBRIDGE.—The following is the speech delivered on October 11, by the Public Orator, Dr. Sandys, in presenting for the degree of Doctor in Science, *honoris causa*, Mr. Samuel Pierpont Langley, Keeper of the National Museum, Secretary of the Smithsonian Institution, and Director of the Astrophysical Observatory in Washington; the inventor of the "bolometer" and the "aërodrome."

Trans aequor Atlanticum ad nos nuper advectus est vir scientiarum in provincia insignis, qui etiam de astronomia recentiore librum pulcherrimum conscripsit. In urbe quod reipublicae maximae transmarinae caput est, viri huiusce curae multa mandata sunt: primum museum maximum rerum naturae spoliis quam plurimis ornatum; deinde institutum celeberrimum scientiae et augendae et divulgandae destinatum; denique arx et specula quaedam stellarum lumini in partes suas distribuendo dedicata. Luminis in spectro, ut aiunt, infra radios rubros radii alii qui oculorum aciem prorsus effugiunt, viri huiusce ingenio, instrumenti novi auxilio quod βολόμετρον nominavit, paulatim proditi et patefacti sunt. Nemo mirabitur virum stellarum observandarum amore tanto affectum, etiam e terra volandi desiderio ingenti esse commotum,—adeo ut, quasi alis novis adhibitis, plus quam trium milium pedum per spatium, etiam avium volatum aemulari potuerit. Fortasse aliquando, Icari sortem non veritus, etiam Horati praesagia illa sibi ipsi vindicabit:—

> "non usitata nec tenui ferar
> penna biformis per liquidum aethera."

Fortasse rerum terrestrium impatiens, rerum caelestium avidus, ausus erit e terris "volare

> sideris in numerum, atque alto succedere caelo."

THE Senate of the reorganised University of London is now complete, and is constituted as follows:—Chancellor—The Right Hon. the Earl of Kimberley. Vice-Chancellor—Sir H. E. Roscoe, F.R.S. Chairman of Convocation—Edward Henry Busk. *Crown Members*—The Hon. W. Pember Reeves, Sir H. E. Roscoe, F.R.S., Mrs. E. M. Sidgwick, Sir John Wolfe Wolfe-Barry, F.R.S. *Faculty Members*—Theology—The Rev. Principal Alfred Cave. Arts—Prof. M. J. M. Hill, F.R.S., Prof. W. Paton Ker, Miss Emily Penrose, Prof. G. C. Warr. Laws—Lord Davey, appointed by the Crown. Music—Sir Charles Hubert Hastings Parry. Medicine—Dr. J. R. Bradford, F.R.S., Dr. J. Kingston Fowler, Dr. E. C. Perry. Science—Sir Michael Foster, Sec.R.S., Dr. William D. Halliburton, F.R.S., Prof. William Ramsay, F.R.S., Prof. A. W. Rücker, F.R.S. Engineering—Prof. W. C. Unwin, F.R.S. Economics, &c.—Prof. W. A. S. Hewins. Royal College of Physicians—Dr. W. H. Allchin, Dr. P. H. Pye-Smith, F.R.S. Royal College of Surgeons—Dr. A. P. Gould, Dr. H. G. Howse. University College—Prof. G. C. Foster, F.R.S., Lord Reay. King's College—Lord Lister, P.R.S., the Rev. Principal A. Robertson, D.D. Lincoln's Inn—Lord Macnaghten. Inner Temple—Judge Sir Alfred Marten, Q.C. Middle Temple—Mr. C. M. Warmington, Q.C. Gray's Inn—Mr. C. A. Russell, Q.C. Incorporated Law Society—Mr. W. Godden, Mr. R. Pennington. Corporation of London—Dr. T. B. Crosby. London County Council—Dr. W. J. Collins, Mr. Sidney Webb. City and Guilds of London Institute—Sir Frederic Abel. *Convocation Members*—Arts—Dr. J. Bourne Benson, Dr. J. D. McClure, Dr. T. Lambert Mears, Mr. J. Fletcher Moulton, M.P., F.R.S., Dr. T. B. Napier, Sir A. K. Rollit, M.P. Laws—Mr. Justice Cozens-Hardy. Music—Mr. J. W. Sidebotham. Medicine—Dr. Thomas Barlow, Dr. J. F. Payne. Science—Mrs. Sophia Bryant, Prof. Frank Clowes, Dr. C. W. Kimmins, Dr. F. S. McAulay, Sir Philip Magnus, Prof. Silvanus Thompson, F.R.S.

THE installation of the Earl of Rosebery as Lord Rector of Glasgow University has been fixed to take place on November 16.

PROF. BRUNHES, professor of physics in the University of Dijon, has been appointed director of the observatory on the Puy-de-Dôme.

MR. HOLBROOK GASKELL has given 1000*l*. towards the building and equipment of a new physics laboratory for University College, Liverpool.

MAJOR R. H. FIRTH has been selected to succeed Colonel J. Lane Notter, R.A.M.C., as professor of Military Hygiene at the Army Military School, Netley.

A FELLOWSHIP of the annual value of 100*l*., for three years, will be awarded at Newnham College, Cambridge, in June 1901. Applications from former students of the college should be sent by May 1 to the Principal, from whom further information may be obtained.

THE Essex Museum of Natural History will be opened at West Ham this evening (October 18) by the Countess of Warwick; and the Municipal Technical Institute, which was destroyed by fire a few months ago, will be reopened by Mr. J. Passmore Edwards.

MR. T. GRAHAM YOUNG, son of the late Dr. James Young, F.R.S., has offered the sum of 10,000*l*. to the West of Scotland Technical College Building Fund, provided that certain conditions are fulfilled as to the site of the new College, the construction of a chemical department, and the completion of the building within five years of next January.

**The** trustees of the College of the City of New York are, according to *Science*, considering the lengthening of the course to seven years. They have asked that the appropriation of 200,000 dollars made to the institution by the Board of Estimate and Apportionment be increased by 25,000 dollars.

**The** Berlin University has, it is stated, decided to alter the conditions permitting foreigners to take the title of doctor of philosophy. Foreigners are only to be allowed to graduate if they hold certificates equivalent to that of the Humanistischer Gymnasium, Realgymnasium, or the Oberrealschule of the German Empire.

**The** *Pioneer Mail*, Allahabad, states that a petition is about to be presented to the Lieutenant-Governor of Bengal asking that the Behar School of Engineering may be affiliated to the Calcutta University. "The one thing," the petitioners observe, "which has hampered the progress of the school in the past has been the uncertainty regarding its future. If Government will now settle the matter finally by raising the school to the status of a College, all obstacles in the way of the development of technical education in Behar will be for ever removed."

**The** new Municipal Technical School which was opened by the Earl of Derby a few days ago, at Bootle, an enterprising borough on the borders of Liverpool, is shown in the accompanying illustration. Classes in science and technology have been held in Bootle since 1891, but the work has been very restricted on account of lack of adequate accommodation. The question of providing a special building for the work to be carried on and developed soon became a pressing one, and in 1897 a suitable site was obtained. In due course tenders were invited, and the handsome and convenient building here shown was erected at a cost of 22,065*l.* Four schools are to be accommodated in the building, viz. (1) the evening school, consisting of many science and commercial classes and some trade or technological classes; (2) a school of art, located in the upper rooms on the Balliol Road frontage; (3) a school of domestic economy placed in a special portion of the west wing; (4) a day-school for boys of twelve years of age and upwards, giving a course of instruction as nearly as possible on the lines of a good secondary or modern high school. The engineering department contains modern machines of workshop size, fitted up conveniently for demonstrating and teaching the essential workshop processes in engineering on a small but useful scale. Of course, a trade will not be taught, for commercial and industrial conditions cannot hold in a school; but care, accuracy, thought, possibly invention, may be developed by the teaching of the grammar of iron-work in the way indicated. In time it is hoped that this branch of the school will need extension and that it may then be possible to equip a mechanical laboratory provided with testing machines and demonstration appliances on a larger scale than can be used in an ordinary class room. As to the cost of carrying out this work under the new conditions, a sum of something like 700*l.* per annum will be required from the rates. Fees, grants and Imperial funds will in all probability contribute about 3,700*l.* per annum. Hitherto no rate has been levied for purposes of technical instruction, and the educational work has been entirely paid for from students' fees and Imperial grants.

The Municipal Technical School, Bootle.

## SOCIETIES AND ACADEMIES.

### London.

**Royal Society**, June 21.—"On the Spectroscopic Examination of Colour produced by Simultaneous Contrast." By George J. Burch, M.A., Reading College, Reading. Communicated by Francis Gotch, F.R.S., Professor of Physiology, University of Oxford.

It is well known that a neutral grey looks blue-green against a red ground and orange against a blue ground. This phenomenon may be spectroscopically investigated as follows:—

A square of red glass is inserted on one side of the central partition of an ordinary stereoscope, and a square of blue glass on the other. Over each eye-lens is fixed one of Thorp's replicas of Rowland's gratings having 15,000 lines to the inch. Two slits are held in a frame in front of the aperture by which light is usually admitted when using the stereoscope for opaque photographs. The spectra of the first order of these slits appear in the middle of the two glasses. In order to prevent direct admixture of the colours of each spectrum with those of the opposite background, two opaque squares of black material are cemented to each of the coloured glasses, so shaped as to appear of the exact size and position of the spectra. On looking through the stereoscope, two spectra are seen side by side on a field, the colour of which continually oscillates from red through purplish-grey to blue. That connected with the red glass shows little or no red, but a splendid green and an equally splendid violet; while that belonging to the blue glass has the red well developed, the green pale and dingy, and the blue almost absent. The effect of varying the nature of the blue screen is very instructive. With cobalt glass the red is not very bright, owing probably to the transmission of some red rays by the cobalt glass, but the addition of a film stained with Prussian blue, by which these rays are absorbed, greatly improves the red. On the other hand, a pale yellow film which cuts off the violet causes the violet of the spectrum on the blue ground to stand out brightly, while a purple film brings out the green, which, owing to the green light transmitted by ordinary cobalt glass, is generally a good deal enfeebled. In each case the contrast of the two spectra seen by different eyes is so well marked that the experiment seems likely to be of service in teaching.

The complementary colour to red is shown to consist, not of one simple colour-sensation, but of two at least, namely, green and violet, and in the author's case of blue also. Against a magenta background the complementary colour is seen to be spectral green. But in this case the physical stimulus is complex. On adding to the magenta a yellow glass, to cut out the violet, or using candle light, the violet reappears in the complementary spectrum, while if a blue glass is added instead, the violet vanishes, and red stands out brightly in the spectrum. It may be thus shown that the colour which has green for its complementary is not spectroscopically simple, and since the spectral elements of it have each a different and independent effect upon the spectrum of the complementary colour, the author concludes that the green sensation has no special connection with the red, or indeed with any single colour sensation.

### Manchester.

**Literary and Philosophical Society**, October 2.—Prof. Horace Lamb, F.R.S. (President), in the chair.—Mr. Thomas Thorp described a method of producing a spectrum-like band from a volumetric curve by the use of a photographic camera with a cylindrical lens, and also gave a brief account of the solar eclipse of May last as seen in Algiers.—A paper on plumbism in pottery workers was given by Mr. William Burton, who dealt with the subject from the technical point of view, showing how the plumbism was caused by the inhalation or swallowing of dust containing soluble lead compounds. It was pointed out that the abolition of lead from the glaze was not a practicable remedy, as leadless glazes suited to the conditions of the general run of English pottery are not yet within the reach of the manufacturers. Further, the abolition of lead from the glaze would not affect those cases which arise from the use of enamel or on glaze colour used in the form of dust or of spray, and no one has yet ventured to suggest that the use of lead fluxes for this purpose could be abolished. The existing remedies in the shape of mechanical means for dealing with the dust in such a way that it should neither be swallowed nor inhaled, the periodic medical examination of the workers, and the proposed further safeguards of converting all the lead used into compounds of considerably lower solubility than those now employed, were also treated of. The final opinion of the author was that the combination of all these safeguards would, within a reasonable time, render the operations of glazing and decorating pottery with substances containing lead compounds as free from risk to the operative as it was possible for any industrial occupation to be.

### Paris.

**Academy of Sciences**, October 8.—M. Maurice Lévy in the chair.—Note on the thirteenth conference of the International Geodetic Association, by M. Bouquet de la Grye. From the reports to the conference it appears that the whole of Europe and North America will be shortly completely covered by a network of triangles. Special observations have been carried out under the direction of the central office in several observatories to determine exactly the line of displacement of the poles. An arc of meridian is being measured in Spitsbergen by Swedish and Russian observers, and Great Britain has commenced the determination of an arc from the Cape to Alexandria, which will join on to the European network through Asia Minor.—Remarks by M. Guyon on the *Connaissance des Temps* for 1903.—Observations of the sun made at the Observatory of Lyons with the Brunner equatorial during the second quarter of 1900, by M. J. Guillaume. The results are summarised in three tables showing the number of sunspots, their distribution in latitude and the distribution of the faculæ in latitude.—The total eclipse of the sun of May 28, 1900, observed at Elche (Spain), by M. Lebeuf. The results of the observations on the times of contact are given.—Researches on the inverse effect of the magnetic field which ought to produce movement in an electrified body, by M. V. Crémieu. The application by Lippmann of the principle of the conservation of energy to the experiments of Rowland on electric convection shows that, reciprocally, magnetic variations ought to produce a movement of electrified bodies placed in the field. The experiments carried out by the author, a detailed description of which, with two diagrams, is given in the paper, show that the expected effect is not produced. The deflection upon the scale should according to the theory have been of the order of 100 to 140 mm. No measurable deflection occurred. Telegraphy without wires with relays. Inconvenience of the Guarini relays, by MM. Guarini and Poncelet.—On iron silicide $SiFe_2$, and on its presence in commercial ferrosilicons, by M. P. Lebeau. A mixture of iron and copper silicide is heated for several hours to the highest temperature of a wind furnace. The mass is extracted with 10 per cent. nitric acid, when a crystalline mass of iron silicide, $Fe_2Si$, is left behind, which is further purified by successive treatment with soda solution, nitric acid and water.—On a new pyrogenous product from tartaric acid, by M. L. J. Simon. An acid, $C_7H_8O_3$, was obtained, differing both in melting point and solubility from the acid of the same composition previously obtained from the same source by MM. Wislicenus and Stadnicki. Its potassium and silver salts were prepared.—Acetyl derivatives of cellulose and oxycellulose, by MM. Léo Vignon and F. Gerin. Cellulose acetylated by means of acetic anhydride and zinc chloride gives a tetra-acetyl derivative; oxycellulose behaves similarly, and the derivative thus obtained clearly retains its aldehydic functions.—The Albien and Cenomanian of Hainaut, by M. Jules Cornet.

## THE ENGLISH GAULT AND UPPER GREENSAND.

*Memoirs of the Geological Survey of the United Kingdom. The Cretaceous Rocks of Britain. Vol. I. The Gault and Upper Greensand of England.* By A. J. Jukes-Browne, B.A., F.G.S. With contributions by William Hill, F.G.S. Pp. xiv + 499. (Published by order of the Lords Commissioners of H.M. Treasury, 1900.)

TO review this book is no easy task. To select is difficult when details are so full; to criticise requires one to have studied, at any rate, certain districts of Cretaceous deposits as thoroughly as Mr. Jukes-Browne, by whom it has been written. So, in regard to the latter, we reserve the right of private judgment only on one or two small matters. A slip of the pen on p. 411, line 47, substituting eastern for western, and the reference to the map at the bottom of the same page (to a less degree) will cause a passing perplexity to readers. But who can help occasionally nodding in passing five hundred pages through the press? To have included the Cretaceous deposits of Scotland and Ireland, would, we think, have made the subject more complete, and not materially increased the number of pages. We think also that Neocomian is big enough and distinct enough, physically and palæontologically, to be released from its subject position of Lower Cretaceous. Surely its claims to systematic independence are as good as those of Oligocene. Yet that has been officially welcomed while Neocomian is slighted. Mr. Jukes-Browne has, however, coined a new, though more subordinate name—that of Selbornian—to include the Gault and Upper Greensand, from the place hallowed by the memory of Gilbert White. We confess to retaining something of primitive man's prejudices against strangers, especially in nomenclature, but must admit that its author makes out a very strong case for the novel term. Briefly stated it is this: During the last twenty years it has been gradually ascertained that the Gault and Upper Greensand in this country are not two distinct stages of the Cretaceous system, but that "the greater part of the Folkestone Gault and the greater part of the so-called Upper Greensand are correlative deposits formed at the same time in different parts of the same sea." As the author shows, uncertainties in regard to their usage prevent us from borrowing either Albien or Cenomanien from the French, and, as a comprehensive term is so much needed, we have no choice but to coin a new one.

In a series of chapters Mr. Jukes-Browne, aided by Mr. William Hill, whose services in the field as well as in microscopic investigations have been of the highest value, describes the Selbornian in different districts. First, however, by way of clearing the ground, comes an introductory chapter on the Upper Cretaceous system as a whole; a second contains an historical account of the Chalk, Upper Greensand and Gault. For purposes of reference, this epitome of various opinions will be very useful, and has probably cost Mr. Jukes-Browne more labour than any other chapter in the book, for tracking down misconceptions and errors is a longer business and less exciting than hunting a fox, while the prey is equally malodorous and worthless. A chapter follows on the value of zones in the Cretaceous system, and another with a general account of the Selbornian. The Lower Gault, the most persistently argillaceous member, is a little over 34 feet thick at Folkestone; it increases to 90 feet at Devizes, is proved by borings to be 150 feet in Bucks, and in Bedfordshire may perhaps be still thicker; thence it thins gradually towards the north-east, till at Roydon, in Norfolk, it is only 7 feet. Afterwards it disappears as a clay, being represented by part of the Red Chalk from Hunstanton to Speeton. It is separable into three zones—that of *Ammonites mammillatus* at the base, thin, sandy, perhaps sometimes absent; then that of *A. interruptus;* the third being that of *A. lautus*. The Upper Gault with part of the Upper Greensand, the zone of *A. rostratus*, is lithologically variable, consisting of marly clays in the south-east, in Bucks and in South Norfolk, it becomes more sandy elsewhere (as in the Isle of Wight, and especially in Dorset and Devon) while in most other parts it is largely composed of the rock known as malmstone. The Warminster Beds, or the zone of *Pecten asper*, arenaceous and containing chert, form the uppermost division of the Selbornian. All have their equivalents in the Red Chalk of Norfolk and the north-east. The third and second are missing in the neighbourhood of Cambridge; while in the west the Haldon Beds begin and end a little later than those of Blackdown.

Details are given of the sections in different parts of England, including those pierced by borings under London and in the Eastern counties, with lists of fossils and information of economic value, while Mr. W. Hill supplies two very interesting chapters on the lithology of the Gault and Upper Greensand. From these and the palæontological data Mr. Jukes-Browne concludes that the Gault clays were probably deposited in a sea, increasing in depth from about 150 to 200 fathoms, the sands of the upper part indicating stronger currents, possibly without any shallowing. He also discusses the physical geography of the period and the direction from which the sediment came. Here perhaps he touches on questions too speculative for an official publication, which should be restricted as far as possible to facts and to such inferences as follow directly from them. In this matter, while accepting Mr. Jukes-Browne's general conclusions as to physical geography, we doubt, for that very reason, whether the mud can have been brought from the south-east. If the region in which it was deposited was then an elongated gulf, open in that direction to the sea, we are unable to understand how an inflowing current of any strength could have been produced. If the gulf resembled the Red Sea, the inset from without would be sufficient to balance evaporation but not strong enough to carry the mud very far; while if it received important rivers, the flow and consequent supply of material would be from the opposite direction. Mr. Jukes-Browne, it is true, refers to the possibility of a return coast current from the north, but we fail to see how, in a gulf of this form, the "blind-cord" action could be set up enough to be a primary agent in the transportation of sediment.

Quitting this very debatable question, we heartily congratulate Mr. Jukes-Browne and the Survey on this instalment of a complete memoir on the Cretaceous rocks of England. The possession of a synoptic view of any one formation is a great boon to geologists, as it saves them from the labour of hunting through a number of separate Survey memoirs. In future it might perhaps be well to shorten those explanatory of the maps by reserving all broader question for volumes like the present one. In this we note with especial pleasure the inclusion of chapters written by a geologist without any official position as an indication that the Survey now welcomes external help. The "get-up" of the volume shows improvement, but there is room for more. The illustrations, for instance, suffer from the thinness of the paper, through which the type can be seen. This defect spoils an excellent outline sketch on p. 152. A few plates, however, are printed on separate paper, and yet the book is issued at a moderate price. Difficult as it notoriously is to overcome the love of saving a ha'porth of tar so characteristic of Treasury officials, we wish the Director-General still greater success in persuading them to come nearer to the level of the volumes issued by the Geological Survey of the United States.

T. G. Bonney.

## *THE PRINCIPLES OF PATENT LAW.*

*The Law and Practice relating to Letters Patent for Inventions.* By R. W. Wallace and J. B. Williamson. Pp. lxv + 922. (London: W. Clowes and Sons, Ltd., 1900.)

THE subject of inventions is always an interesting one whether to the manufacturer or to the man of science, nearly all new improvements in commercial chemistry or mechanics being, in these days of vigorous competition, sought to be protected by Letters Patent. Whether the English system of patent law is entirely satisfactory in all its details is a matter on which there are many opinions, and the Committee now inquiring into this may possibly suggest some alterations being made.

As a guide to the existing state of the law up to the most recent decisions in the Courts, Messrs. Wallace and Williamson have issued this volume, which may be called a treatise rather than a text-book. The arrangement and division of the subject is clear; starting from the granting of the Letters Patent, the reader is carried on to what is required of an inventor to render the grant valid and up to the petition for extension. Very little attention is given to the past history of the law, only a few pages being devoted to the well-known cases of the early part of the seventeenth century and a few remarks made on the history of claims. On the difficult subject, in which every discoverer of some new process must be interested, of what is necessary to constitute a patentable invention, the authors have not attempted to lay down any definition of their own, but have devoted two chapters to a careful collection of the important decisions on the point. In fact, throughout the book there is given the material for forming an opinion rather than definitions.

For those who have not a well-stocked library of law-books there is the very great advantage that this volume gives verbatim extracts of nearly every important case, and even for those who have the books at command it will often save them the trouble of hunting up the passages they most often need. For those professionally interested in the subject there is a full and accurate account of the various steps in an action for infringement, which is very clearly set out; and after 600 pages of text there are some 250 of appendices containing the various statutes, together with forms and precedents for almost every conceivable case.

The principles upon which the specifications and claims should be drafted are adequately dealt with, and the question of amendment is gone into. There is a short chapter on the procedure on petitions for compulsory licenses, which procedure, curiously enough, does not appear to have attracted the attention of those who would be likely to benefit by it until within the last two or three years.

The printing of the work has been well done in large type and on good paper, the headings to the various paragraphs being sufficiently clear. A conspicuous feature of the work is the full index and the table of cases, which gives with each case the date of the decision and the subject-matter of the patent decided on. The book may confidently be recommended to any one desiring a complete account of the principles upon which our system of patent law is founded, as well as to those who constantly require a trustworthy book of reference.

## *HISTORICAL CHEMISTRY.*

*Lectures on the History of the Development of Chemistry since the Time of Lavoisier.* By Dr. A. Ladenburg. Translated from the second German edition by Leonard Dobbin, Ph.D., with additions and corrections by the author. Pp. xvi + 373. (Edinburgh: Published for the Alembic Club by W. F. Clay. London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1900.)

THE small knot of chemists in Edinburgh who constitute the Alembic Club have already earned the thanks of chemists by placing at the disposal of English readers their valuable reprints of important chemical memoirs, a series which it is hoped may run on long and, if possible, at an increasing rate. The present volume is a more ambitious undertaking, being the translation of a substantial work which has long enjoyed much favour in Germany as a lucid and not too bulky account of the development of modern chemistry.

English chemical literature is not rich in original historical writing, though there are at least one or two British chemists who may be looked to with confidence for the occasional production of a scholarly and readable contribution. Going back a long way, it may be said that Thomas Thomson's "History" is inferior to no book of the kind published since—in respect to literary style and readableness. But in those days the science was narrower, and it was well within the ability of one man to do justice to the whole subject. The exhaustive historical writings of Hermann Kopp, and the more recent contributions of Berthelot, leave little to be desired in completeness, and provide a repository of information invaluable for purpose of reference. This, however, is literature for the fully fledged chemist or chemical author.

The chemical student requires something different. The importance to him of attending to the historical aspect of chemistry is recognised by most teachers. It is indeed maintained by some that there is no other satisfactory way of approaching even the elements of chemistry, than by performing experiments in historical order. A Board School might be cited where the older boys are given the Alembic Club reprints, and asked to do the experiments as there described. Whatever may be thought of this, it cannot be denied that a study of chemical history is most important, not only for a clear grasp of the origin and growth of our present theories, but because of that more subtle influence on the mind and imagination which perhaps may be included in the much-abused word culture.

The full advantage of historical study is not to be obtained by the reading of such a work as the one under notice, but rather by the careful study of those original memoirs or books which will ever remain landmarks in the track of scientific progress. At the same time, a connected history is a useful and perhaps a necessary adjunct to these partial studies, and this want is met extremely well by the book under notice.

Prof. Ladenburg has cast his story in the form of lectures, and for the purpose in view this is a satisfactory arrangement. In tracing the history of chemistry from the time of Lavoisier to the present day a vast amount of material has, of course, to be dealt with; and of the prodigious amount of reading and critical examination entailed upon the author there is abundant evidence both in the text and in the numerous references which are appended. As to the general balance of the book it may be said that the earlier part is fuller and more explanatory than the later. The account, for example, of the controversy between Berthollet and Proust is very clear and interesting, whilst the accounts of the controversies that raged later in the century in regard to fundamental questions of organic chemistry are much more compressed and difficult to follow. The last chapter of the book is little more than an enumeration of the chief chemical topics that have engaged attention during the past fifteen years.

However, looking at the book as a whole, it must be said that Prof. Ladenburg has produced a most useful history, extremely readable considering the inevitable compression, remarkably free from the bias of personal opinions, and giving a connected view of the progress of chemical science which will be of great benefit to students.

Dr. Dobbin has succeeded admirably in the arduous work of translating narrative German into narrative English. Here and there sentences are to be found which declare their origin; but on the whole the English (or should one say British?) flows smoothly, and there is a remarkable absence of typographical errors or mistakes of a more serious kind. Dr. Dobbin and the Alembic Club may certainly be congratulated on their latest contribution to chemical literature.

A. S.

## OUR BOOK SHELF.

*Untersuchungen über Mikrostrukturen des erstarrten Schwefels nebst Bemerkungen über Sublimation, Überschmelzung und Übersättigung des Schwefels und einiger anderer Körper.* By O. Bütschli. Pp. iv + 96; 4 plates. (Leipzig: W. Engelmann, 1900.)

*Untersuchungen über die Mikrostruktur künstlicher und natürlicher Kieselsäuregallerten (Tabaschir, Hydrophan, Opal).* By O. Bütschli. Pp. 287–348; 3 plates. (Reprinted from *Verhandl. d. Naturhist.-Med. Vereins zu Heidelberg*, N.F. Band vi. 1900.)

A previous work by the professor of zoology at Heidelberg ("Untersuchungen über Strukturen," 1898), reviewed in Nature (vol. lx. p. 124), dealt more especially with the microstructure of organic substances, comparing them with the supposed alveolar structure of protoplasm. In the first of the present pamphlets the author describes in minute detail his observations in the same direction made on inorganic substances, more particularly sulphur. Amongst the various globular and crystalline forms produced by the sublimation and subsequent transformations of sulphur, he describes some which have a radial or concentric arrangement of vacuities or air-spaces suggesting an alveolar structure. The subject is, however, treated throughout from a crystallographic rather than from a biological point of view, and much the same ground has been covered in a more concise and earlier paper by Dr. R. Brauns, the professor of mineralogy at Giessen ("Beobachtungen über die Krystallisation des Schwefels aus seinem Schmelzfluss," *Neues Jahrb. f. Mineralogie, &c.*, 1899, Beil.-Bd. xiii. pp. 39–89; 7 plates).

The second pamphlet describes with equal minuteness the appearances shown under the microscope by chips and thin sections of dried gelatinous silica, as well as of the natural forms of colloidal silica, tabasheer and opal (including hydrophane and precious opal), which are all very similar in their minute structure.

Both pamphlets are admirably illustrated with numerous well-prepared microphotographs.

*The School Journey. A Means of Teaching Geography, Physiography and Elementary Science.* By Joseph H. Cowham. With additional "Journeys" by G. G. Lewis and Thomas Crawshaw. Pp. 79. (London: Westminster School Book Depôt, 1900.)

For many years the study of geography at the Westminster Training College has been supplemented by an excursion from Croydon to Godstone, under the guidance of Mr. Cowham, the lecturer on education at the college, and the author of several excellent educational works. In this volume a description is given of the chief characteristics observable during the ramble; and horizontal and vertical sections, as well as photographic illustrations, elucidate the physical geography of the district traversed. In addition, the book contains accounts of excursions to Greenwich and Woolwich, and along a river bank in Lancashire, contributed by two of Mr. Cowham's former pupils.

The book appears at the right psychological moment; for the feeling that geography should, whenever possible, be made an outdoor study, is spreading, and every statement of experience is of value to teachers who want to improve methods of instruction in geography but are unable to see clearly how to carry out schemes which have been put on paper by persons who may not have given full consideration to ways and means. Here, however, we have notes upon actual excursions and how they were planned and performed, and with these before them, teachers should have no difficulty in arranging others if they have some knowledge of physical geography. The Geologists' Association and Prof. Seeley's Geological

Field Class provide teachers in London or the neighbourhood with exceptional opportunities for acquiring a knowledge of the significance of the geological structures and formations in the home counties, and Mr. Cowham's book will show them how the facts can usefully be applied to school excursions.

*Air, Water and Food.* By Ellen H. Richards and Alpheus G. Woodman. Pp. 226. (London: Chapman and Hall, Ltd. New York: John Wiley and Sons, 1900.)

Of the many volumes which have been written on these subjects, there are few which, in the opinion of the writer, can be more safely recommended to the student of sanitary science. Each of the three subjects is introduced and fairly discussed in language which is clear, trenchant and concise.

The authors are, moreover, no mere theorists, but describe the operations of the laboratory in a business-like fashion which leaves no doubt about their practical knowledge. The diagrams are more successful as illustrations than the photographs, in which, as frequently happens, the glass apparatus has such an ill-defined and ghost-like appearance as to be unrecognisable by the unprofessional eye. In other respects the book is well got up. J. B C.

*Elementary Physics and Chemistry*, ii., iii. By R. A. Gregory and A. T. Simmons. Second stage, pp. vi + 140; third stage, pp. vi + 114. (London: Macmillan and Co., Ltd., 1900.)

These two volumes complete a work of three parts, consisting of a course of experimental illustration of the elementary principles of chemistry and physics. The syllabus of subjects considered is based on the new Code issued by the Education Department, but the descriptions are by no means confined to it. The subject-matter is arranged in the form of a succession of separate gradated lessons, each consisting of description of apparatus, method of conducting experiment, results obtained and the reasons for them, short summary, and a set of exercises. The books thus arranged seem especially valuable to teachers having to give a comprehensive course in a definite number of lessons—in Evening Continuation Schools, for instance—as the whole work to be gone through may be at once divided into sections. Numerous excellent illustrations add considerably to the utility of the volumes. C. P. B.

*Principes D'Hygiene Coloniale.* Par Le Dr. Georges Treille. Pp. iv + 272. (Paris: Georges Carré et C. Naud, 1899.)

This useful little volume is addressed particularly to those who wish to inform themselves of the physical conditions of life in the tropics with a view to living there, and to those who have an indirect interest in tropical regions. The earlier portion of the volume deals with tropical climatology in general, and in particular with the climatology of the French colonies. A chapter is devoted to considering the action of the climate on bodily functions. The latter portion deals with public and domestic hygiene. In the discussion on European habitations in the tropics, one would have wished to see more stress laid on the importance of Europeans living apart from the natives—a custom which has been so universally adopted in India, and which no doubt accounts to a large extent for the comparative freedom of Europeans from malaria in that country.

We fully endorse the indictment of the use of alcohol specially in the form of absinthe, but we should have liked to see more information on measures to be taken to ensure a supply of good water for domestic purposes.

C. B. S.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

### Genesis of the Vertebrate Column.

In the review of "The Foundations of Zoology," by Prof. W. Keith Brooks, which was contained in the last number of Nature, the reviewer quotes from him the following sentence:—"Herbert Spencer tells us that segmentation of the backbone is the inherited effect of fractures caused by bending."

Before the reader accepts this version of my view, he would do well to read §257 of "The Principles of Biology." The simplest expression of that view is contained in the criticism of Prof. Owen's "Theory of the Vertebrate Skeleton," originally published by me in the *British and Foreign Chirurgical Review* for 1858, and now appended to "The Principles of Biology." The sentence setting it forth runs thus:—

"The production of a higher, more powerful, more active creature of the same type, by whatever method it is conceived to have taken place, involved a change in the notochordal structure. Greater muscular endowments presupposed a firmer internal fulcrum—a less yielding central axis. On the other hand, for the central axis to have become firmer while remaining continuous, would have entailed a stiffness incompatible with the creature's movements. Hence, increasing density of the central axis necessarily went hand in hand with its segmentation; for strength, ossification was required; for flexibility, division into parts."

There is here no mention or thought of "fracture"—no implication of a dense part formed and then broken, but the implication of dense matter being deposited in successive separate portions, in such way as to fulfil the two requirements of strength and flexibility. Herbert Spencer.

Brighton, October 21.

### Albinism and Natural Selection.

A case of partial albinism in fishes which has recently come under my notice is likely to be of general interest from the evidence it apparently affords of the value of the normal specific coloration of predaceous fishes, and of the serious disadvantage of conspicuous abnormalities.

A white-skinned specimen of the common hake (*Merluccius merluccius*, L.) was trawled in the Bristol Channel last week amongst a catch of normal hake, and was sent to me from Milford immediately on landing, owing to the fishermen's impression that it belonged to some rare species unknown to them.

It was, however, perfectly normal in all respects except its remarkable leanness and the absence of all pigmentation from the external skin and the inner lining of the buccal cavity and gill-covers. The pigmentation of the retina and peritoneum was normal.

In a normal hake there is a profuse black pigmentation over the upper part of the body, as well as over the inside of the mouth and gill-covers. The general appearance of a normal hake is consequently dusky; that of the abnormal specimen was white.

The lean and emaciated condition of the white hake was very striking, especially in the head region, where not only the bony ridges of the skull and cheeks projected sharply beneath the thin layer of skin, but even the lines of sculpture of the superficial bones were plainly recognisable. In a normal hake, of approximately equal length, with which I compared the specimen, these details were quite invisible, and the bony ridges were rounded off or hidden by the plumpness of the integument. In girth and weight the albino was far inferior to the normally pigmented fish. The albino measured 26¼ ins. in length to the base of the caudal fin, and 6¼ ins. in length of head (from snout to opercular spine). Its girth round the back of the head was 9 ins., and just behind the 10th anal finray 9⅛ ins. The normal hake measured 27½ ins. in length, and had the same length of head as the albino. Its girth in the same two regions was 10⅛ ins. and 10¼ ins. respectively. The albino weighed 4 lb. 5 oz., the normal hake 5 lb. 9½ oz., both fish being gutted in the same way.

That is to say, although the length of the albino was only 4½ per cent. less than that of the normal hake, the deficiency in girth amounted to 11 per cent. and the deficiency in weight to 23 per cent.

The question arises whether the emaciation of body, and lack of pigmentation, should be regarded as results of some disease (which was not otherwise apparent); or whether the lean condition should be attributed to the insufficient nutrition of a predaceous fish whose stalking powers had been reduced by its conspicuous appearance.

The hake is a predaceous and nocturnal fish, which preys on mackerel, herring and other active fish, especially at night.

The bulk of evidence appears to favour the view that albinism in fishes is a congenital, and not an acquired character (*cf.* colour variation in flat fishes); and I am not aware that leanness of body is specially correlated with the albino condition.

Perhaps some of your readers could refer me to other records which would throw light on this case?

Plymouth, October 10. Walter Garstang.

### Tenacity of Life of the Albatross.

Sir William Corry told me some time ago that on one of his steamships coming from New Zealand, an albatross, supposed to have been choked dead, kept in an ice box at a temperature which was always much below freezing point, was found to be alive at the end of fourteen days. He has been kind enough to obtain for me the following statement in writing from Captain Reed. Of course the birds mentioned in this statement could not really have been choked dead, but I think the facts are very interesting. John Perry.

October 11.

The bird referred to was supposed to be killed by being strangled with twine tied as tightly as possible round the neck. This twine was not removed. The beak was closed and tied and the legs crossed behind the tail and tied. It was then wrapped in an old meat cloth and put with three other birds in the return box at the end of the port snow trunk. It remained there for certainly not less than ten days at a temperature of from zero when machine blowing on that side to 18° F. when blowing on the starboard side. The snowboy complained that the bird "grunted" when he went near it with his lamp, and Mr. Coombes, the 1st Ref. Eng. brought it out. When put down on the engine-room floor, it could move its neck about and open its beak, and the eyes were open and lifelike. The lower half of the body and the legs were frozen hard. The fastening on the beak had come off. It was alive for two hours after being taken out, and was then strangled and put in the snowbox.

There was another bird treated in the same way, and hung up by the beak in the meat chamber for over four days, and then found to be alive and able to make a "grunting" noise. The temperature of the chamber was never higher than 4° F., and often 8° to 10° below zero. Mr. Coombes, then 1st Ref. Eng., now in *Star of Australia*, and Mr. Boyes, then 2nd, now 1st Ref. Eng., both declare this to be quite true.

If opportunity offers on the passage home I will try how long it is possible for these birds to live in these low temperatures,

*S.S. Star of New Zealand*, Wellington, Wm. J. Reed.

August 22.

### The Peopling of Australia.

In the issue of Nature for October 4, Mr. J. Mathew has questioned the accuracy of certain observations upon the linguistic part of his book, "Eaglehawk and Crow," which were made by me at the request of Prof. A. C. Haddon, and included by him in the review of Mr. Mathew's book in Nature for December 28, 1899.

I shall be glad if you will permit me to reply as briefly as possible to the complaints in Mr. Mathew's letter.

Mr. Mathew charges me with being "unnecessarily caustic" in my remarks on his theories, and with attending to "petty points" instead of the main issues. To the former charge I must plead zeal for accuracy, and fear of the formation of hasty conclusions. To the second I may be allowed to say, that as the whole of Mr. Mathew's theory (linguistically at least) is based upon the "petty points," their accuracy is vital to the whole structure. Although on p. 44 of his book Mr. Mathew disavows the fallacy that "likeness of words in sound and meaning is a proof of a common origin," he nevertheless adopts it in very many of his comparisons. Take, for example, the Malay and Central Australian words on p. 59; the south-west Australian and New Guinea words on p. 72, the examples in his chapter on the Malay element in Australian, and the satisfaction expressed in his letter to Nature at a comparison between Australian, Malay and New Hebridean, because the "terms for father and skin are the same."

My summary of his chapter on the Malay element in Australian is quoted by Mr. Mathew in his letter as "ridiculous nonsense." I maintain that it is a perfectly fair summary of his actual words. He states on p. 5 that "Malay refers generally to the people of that race to the north of Australia without distinguishing nationality," and on page 61 that the Malay invasion came from the north. Speaking of the invaders, he says on page 61, "The straggling stream winds about here and there, touches the shore at various places and recoils back inwards," but when I state that the meaning of this is "wandering about the interior," he says the latter phrase is a "pure invention of Mr. Ray's."

Although Mr. Mathew declares in his letter that the Malays came from an indeterminable (though probably Sumatran) locality, all the Malay words in his proofs are those of the current literary or colloquial Malay, and several of them (*e.g.* tangan, gigi, kapala, bapa, rambut), are by no means the common words used by the Malayan peoples of the Archipelago. In two instances his words are incorrect: *kaka* is wrongly given *kaku* (p. 59), so as to agree with Australian words like *koko*, *kahkooja*, and '*duwan*' (p. 60), said to mean 'ear' is probably meant for *daun*, "leaf," which only means the "external ear," *i.e.* the 'leaf of the ear,' when conjoined with *telinga*.

That Mr. Mathew believes the Malay words were "scattered all over the island continent" plainly appears from his examples. He shows so-called Malay words on the coast of New South Wales, East Queensland, and the extreme east (p. 58); others across the centre of Australia from the Gulf of Carpentaria southward, and on Cloncurry River (p. 59), and others in West Australia (p. 60).

Mr. Mathew states that in the *Journal* of the Anthropological Institute for 1894–5, I have used languages as the basis of a classification of the New Guinea Islanders. That is so, but my method is not comparable with Mr. Mathew's. I showed that certain New Guinea languages (Motu, Keapara, &c.) should be called Melanesian because they agreed with the languages of the Melanesian islands, *almost entirely in grammar, and very largely in vocabulary*, and that others should be called non-Melanesian because they had *no agreements whatever* with the Melanesian. Can Mr. Mathew show by a similar grammatical and lexical comparison, that the Australian is related to any other group of languages? With regard to terms like 'bapa' and 'mama' for 'father' and 'mother,' my argument was that no dependence can be placed on these words to show a connection of languages. They are among the earliest vocables uttered by a human being, and in very many languages of the world have become appropriated to the earliest recognised human relationships.

This is not the time or place to reply to the somewhat contradictory propositions in Mr. Mathew's letter. He wishes me to prove: (1) That words of 'mama' type are not adopted words in Malay; (2) that they were not earlier in use in the East Indian Archipelago; (3) that they are not more markedly Papuan than the 'bapa' type. I may, however, be permitted to remark: (1) That words for father containing the syllable *ma* (of which *mama* is a reduplication) are the commonest in the vocabularies of the tribes of Borneo, Celebes, Philippines, &c., least subject to Malay influence, whilst words containing the syllable *ba* or *pa* are confined to the nearest connections of the Malay. Hence the words of *ma* (or *mama*) type are the original, not adopted words, and (2) were necessarily the earlier in use. Mr. Mathew's second proposition thus contradicts his first. Also (3), the languages of the Papuans in West New Guinea have forms of *bapa* for 'father,' those in Central New Guinea have *babe* or *apai*. One Papuan and all the Melanesian have forms of *ma* (*ama* or *tama*).

Mr. Mathew complains that I have not explained the New Guinea numerals. Could I do this within the limits of a review? The convergence of Australian forms towards Cape York, stated by Mr. Mathew, does not necessarily imply that the words came from New Guinea, and his examples only show that the Saibai numeral *may be* connected with the Australian. On the opposite New Guinea coast the numerals for 'one' are very different to the Saibai *urapon*. They are: *nambi* (Morehead River), *ambior* (Wasi Kasa), *tarangesa* (Bugilai Tribe), *iepa* (Kunini Tribe), *atanok* (Dabu Tribe), *netat* (Murray Island), *nao* (Kiwai Island), *monou* (Purari Delta), *farakeka* (Papuan Gulf), *aia* (Yule Island). Mr. Mathew asks us to believe that the Kalkadoon numeral "*luadi*" (two) is a Melanesian numeral used in Australia 150 miles south of the Gulf of Carpentaria, when the only comparable form in Melanesia is the Duke of York Island *ruadi* (second). This is a flagrant example of the method adopted, though disavowed, by Mr. Mathew.

The point missed by Mr. Mathew in discussing the phrase "*ori kaiza*," which I called mongrel, is that he has no proof that '*ori*' and '*uroi*' are the same words. Considering that the Gulf tribes have a word (*uiva*) for 'cassowary' (the emu is not found), and that nowhere else in New Guinea is there a word similar to *ori*, meaning 'bird,' and also that it requires a Torres Straits word to give '*ori*' an Australian meaning, it is highly improbable that it can explain words like *waitch*, *wadgie*, *warritch* for "emu." The Saibai for 'big bird' is '*koi urui*,' for 'cassowary,' '*samu*.'

In his letter, Mr. Mathew objects to my calling comparisons of Australian with Malay and New Hebridean "absurd and misleading." He suggests, without any warrant, that I find the absurdity in analogies between Malay and New Hebridean, whereas I have directly affirmed the connection of Malay with Melanesian (including New Hebridean) in the *Journal* of the Polynesian Society for 1896. The real absurdity is that of supposing that there is a relationship between Australian, Malay and New Hebridean, because "the terms for father, skin are the same."

In conclusion, I must again express my regret that Mr. Mathew should regard my criticism of his work as 'mere fault-finding and ridicule.' I have studied these languages for many years (without postulating theories), and have much material yet unpublished. To point out the weakness of Mr. Mathew's argument, with regard to method and deductions is fair criticism, and should not lead to a charge of unsoundness and inaccurate knowledge. If, as Mr. Mathew states, his materials are imperfect, why found a theory upon them?

## *RECENT AND PROPOSED GEODETIC MEASUREMENTS.*

In the history of geodesy and the discussion of the problem of the figure of the earth, the measurement of three arcs of meridian stands out conspicuously. These are the Peruvian and Lapland arcs in the Northern Hemisphere, and that of Lacaille in the neighbourhood of the Cape of Good Hope. Those who took part in the original measures worthily distinguished themselves, but it is inevitable that with the demand for greater accuracy in geodetic inquiries the necessity for repeating the ancient measures should be acknowledged. Without experience and with imperfect instruments, it is remarkable that the old astronomers accomplished what they did. To determine the approximate figure of the earth, and to derive a fairly accurate value of the compression was no mean achievement. But Lacaille's arc of meridian soon fell into disrepute, and other measures have had to be substituted by Maclear and others. Svanberg repeated the original work of Clairant and his colleagues, in Lapland, soon after its completion, and within these last few years a new determination of the Peruvian arc has been imperatively called for. There is no doubt but that the French nation, who have so honourably distinguished themselves in the difficult task of geodetic measurement, will be able to undertake this work, and increase their scientific reputation. From 1734, when the enlightened Government of the day undertook the measurement of two of the aforementioned arcs, down to our own time, when we have seen the Mediterranean successfully bridged by a geodetic survey, and the interior of Africa connected in one unbroken chain with our own Shetland Islands, French men of science have played a conspicuous part in all questions connected with the true figure of the earth. At a moment therefore when the remeasurement of the famous arc of Peru has been forced upon us, it would have been with a feeling akin to disappointment if we did not find the French nation eager to repeat the historic work with all the skill that long experience has suggested, and all the accuracy that modern science demands. The report of a committee of the French Academy of Sciences, however, assures us that the ardour displayed by the French in the past is no whit abated, and that though the sacrifice of time and money is considerable, these drawbacks will be cheerfully borne. For the arc in Lapland another has been substituted on the Island of Spitsbergen, and the necessary work of triangulation has been for some time quietly carried on under the auspices of the Russian and Swedish Governments; while at the same time, the reports of Her Majesty's Astronomer at the Cape of Good Hope tell us what is being done in the way of supplementing Lacaille's arc in the Southern Hemisphere. With this activity before us, it seems a fitting opportunity to compare the aims and the motives that inspired those who inaugurated the earliest geodetic expeditions with those that will influence and guide the latest surveys in the same or similar regions.

In the middle of the last century a distinct issue was presented to the scientific mind. Then the general figure of the earth was an undetermined problem, and whether the polar or the equatorial axis was the longer was a vexed subject of controversy. It is amusing enough now to read of the disputes between the partisans of defective observations on the one hand, and the upholders of an incomplete theory on the other. To-day no such broad issue is before us, the differences are of a more subtle character, demanding great nicety of observation and more effective analysis. Then the true difficulties of the problem were scarcely apprehended. Only a few years earlier, Fernel had attempted to determine the length of a degree by counting the number of revolutions of his carriage-wheel between Paris and Amiens, a method which recalls the earliest attempts of Eratosthenes. Picard, it is true, had recognised the necessity of employing means of greater accuracy, and had taught the true principles of geodetic measurement; but the methods pursued by his descendants, and the precautions taken to ensure accuracy and recognise the surface to which the measurements are referred, constitute almost a new science. For with accumulating materials and greater experience, it has become necessary to distinguish between three surfaces. First, the ellipsoid of revolution, which corresponds most nearly to the form of the earth; secondly, the true geoid, that is to say, the surface of equilibrium of water at rest under the influence of centrifugal force, and the attraction of the earth's mass; and, thirdly, a corrected geoid, differing but slightly from the true, in which it is attempted to eliminate the effect of unequal masses on the earth's surface and in its interior. Theory shows that the true length of the arc of meridian, measured on the corrected geoid, will be given in terms of the measured base, if the effect of local attractions has been correctly determined. It is precisely in overcoming the difficulty of correctly eliminating the effect of local attractions, and of reducing the length of the measured base to the level of the water surface of the geoid, that the measurements of this century will mainly differ from those of the last.

A preliminary survey of the district undertaken by Captains Maurain and Lacombe has shown that the country of Peru possesses peculiar difficulties for an accurate geodetic survey. The levels vary very considerably with the distance from the coast, while here and there mountains of a volcanic character rise to a height of 6000 metres. But for the interest attaching to a historic site, and the desirability of continuing measurements outside middle latitudes to which they have hitherto been almost entirely confined, a project involving so many hardships might well be abandoned. Not the least interesting part of the report of Captain Maurain is his description of the country in which the pioneers of the last century carried out their observations, often on the slopes of mountains rising abruptly to the height of some 3000 metres. Of this monumental work scarcely a vestige remains, and the original line of route can be traced only from the written records. The care with which the fundamental points in a triangulation are now marked was not appreciated in those early days, and even the pyramids constructed to commemorate the ends of the arc, and the successful termination of the work, have been demolished by the Indians, who hoped to find buried treasure under the monuments, though the jealousy of the Spaniards has led to almost equally deplorable results.

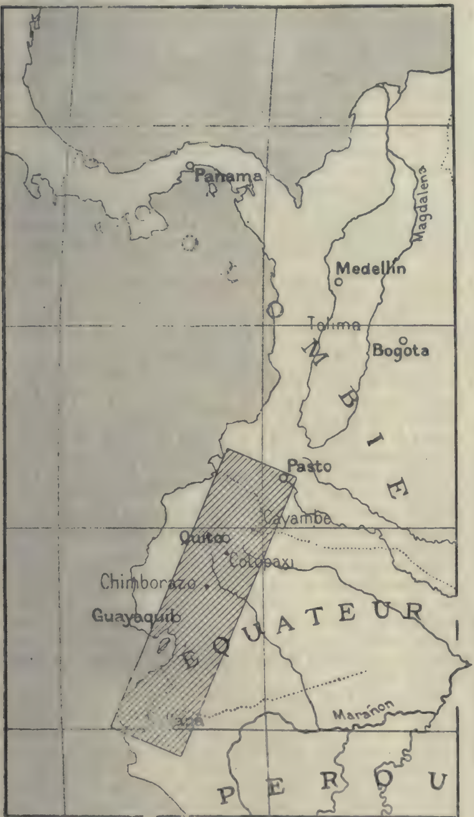

Fig. 1.—The shaded portion of the map shows the district in which the measurements will be made.

But the enterprise of the French will not be contented with the simple re-measurement of the arc of Bouguer, which extended from the environs of Quito on the north to Cuenca, somewhat south of Guayaquil (Fig. 1). Captain Maurain's instructions led him to examine the country north and south of these stations, with the view of extending the arc to six degrees of latitude. In neither direction does the task become more simple. Towards the north the two chains of the Cordilleras unite in a confused mass, bristling with numerous summits, rising to an altitude only less than that of Chimborazo or Cotopaxi. On the southern side the country becomes more open, but covered with forests, and with a wet climate, suggestive of fever. Nevertheless, it seems possible to push northwards as far as Pasto in Columbia, and southwards to the Peruvian town of Sullana, an arc of six degrees, or about double that originally measured. The Finance Minister asks, as Finance Ministers will, whether it is absolutely necessary to carry the arc beyond the limits of the ancient survey, and the answer of the French Academicians, as might have been anticipated, is to insist on the maintenance of the whole scheme as contemplated in the preliminary examination.

The entire programme is vast, and worthy the best traditions of French science. Three bases of about eight or nine kilometres in length will be measured, one approximately central, and two of verification at the north and south ends respectively. The difference of level between the central base and the sea at Guayaquil, where tide gauges will be erected, will be determined with the greatest nicety. Throughout the arc fifty-two stations will be selected for observation, of which three will be fundamental, and the longitudes be determined by telegraph. Magnetic observations will be carried on as a matter of course, and in a country marked by so many mountain masses special care will be taken to determine their extent and density, with the view of eliminating the effect of local attraction. But, after all precautions, it is not impossible that the measures be made on a lengthened protuberance on the surface of the geoid, and that the curvature of the line of route should differ sensibly from that which would be found along a line nearer to the Pacific or further inland. To decide this point, two methods are proposed—one by means of pendulum observations, which will give the variation of gravity throughout the whole region; the other, by determining the difference of geodetic and astronomical longitudes between a point on the coast and the observatory at Quito. The army of experts who have examined the plan and arranged the details assures us that no difficulty has been overlooked, and as a result an admirably equipped expedition will leave France next spring, to take up quarters on the equator, where four years' hard and anxious work awaits the members.

As already mentioned, towards the polar end of the quadrant the expedition under the Russians and Swedes has already made good progress. The arc measured by Maupertuis and Clariaut extended through only fifty-seven minutes in the latitude 66°, and Svanberg attempted no greater distance than $1\frac{1}{2}°$. But the modern scheme includes an arc of more than 4° in length, in the much higher latitude of 77°–81°. The general control is in the hands of H. Sergieffsky, and trained as he has been in the accurate school of Pulkowa, admirable results may be expected. The difficulties to be encountered are probably not less, though of a different kind to those that await the French in the tropics. Fifty stations will be occupied in the course of the triangulation, which compares satisfactorily with the fifty-two of the French scheme. Two base lines only will be measured, in which it is proposed to use Jäderin's steel tape line twenty metres long. Very little is known of the success that has attended this method, though its accuracy is vouched for by Dr. Döllen's careful examination, and the French prefer to rely upon the same apparatus that was used in the determination of the French meridian. It was expected that the field-work in Spitsbergen would be finished this summer, but we are still waiting information concerning the amount of progress that has been made.

Lacaille's arc of meridian, measured in 1752, and practically the only measurement effected in the Southern Hemisphere, was long a subject of perplexity in all theoretical investigations of the figure of the earth, since the result indicated that the earth's surface was less curved in the Southern than in the Northern Hemisphere; but though the verification of the arc was an urgent necessity, it was not till 1840 that Sir Thomas Maclear commenced the work that solved the difficulty. The apparently anomalous result offers a good instance of the effect of local attraction in disturbing astronomical latitudes. The astronomical amplitude of Lacaille's arc (1° 12′) was proved to be very nearly correct, but a large local disturbance of the direction of gravity at the northern end caused a zenithal error of some 8″. Maclear enlarged the arc to nearly 5°, and here geodetic operations practically ceased, till the present astronomer, Sir David Gill, developed a scheme which dwarfs into insignificance all previous measures, and which, if it can be carried out, will prove of the utmost scientific value. He regards all that has been accomplished in South Africa as the first step in a chain of triangulation which, approximately traversing the 30th meridian of east longitude, shall extend continuously through Africa to the mouth of the Nile. He would make his chain follow, or rather precede, the line of that taken by Mr. Rhodes's transcontinental telegraph, proceeding northwards along Lake Tanganyika, through the region of the Lakes Albert and Victoria Nyanza, and along the Nile Valley. The definite survey of Egypt has not yet been undertaken, but commercial and political motives will doubtless soon bring this within the domain of practical science, and assist the onward progress of the scheme. Sir David Gill does not stop at the shores of the Mediterranean. Onwards, by an additional chain of triangles from Egypt along the coast of the Levant and through the isles of Greece, he would connect the African arc with the existing European systems, till it reached an amplitude of 105°. Sir David Gill puts before us a number of considerations by which such a scheme might be carried to a successful issue, without by any means minimising the difficulties which his experience teaches him stand in the way. It is not necessary to dwell on these obstacles, some of which are sufficiently obvious. It should, however, be remembered that no other meridian offers greater, if equal, facilities, or furnishes a better prospect for the realisation of this magnificent scheme. Sir David Gill has not confined his attention merely to the elaboration of schemes; he has accomplished much good work himself, often with straitened means, and by his personal influence and indefatigable energy aided and encouraged others. Under his auspices a chain of triangles has been carried eastward from Cape Town to Port Elizabeth, whence two branches have been carried to the north, one ending at Kimberley, while the other, crossing Natal, stops for the present at Newcastle in the extreme north of the colony. Much exploring work, hardly inferior in point of accuracy, has been carried through Bechuanaland and northwards along the 20th meridian, marking the boundary between German and British South Africa. His latest report tells us that on the eastern side of the continent stations were occupied from Bongwe (Lat. 19° 51′ S., Long. 30° 19′ E.) to a point in 16° 30′ S., and within sixty miles of the Zambesi. There the smoke from extensive grass fires compelled stoppage of field-work for the season, and his party retired to the observatory to occupy themselves in the work of reduction. The outbreak of the war and interruption by the Boers of telegraphic communication with Cape Town have for the moment delayed the determination of longitude of distant stations, but we may be sure that once the country has settled down to normal conditions, Sir David Gill will be ready to prosecute his scheme with the ardour that has ever characterised his undertakings.

## *RECENT ANTARCTIC BOOKS.*[1]

THE long-continued neglect of Antarctic exploration has given place to a period of great activity. Several expeditions have, during the last five years, been hovering on the margin of the unknown, and penetrating within it a few steps farther than their predecessors. Great preparations are being made for what ought to prove the most determined effort to explore and study those regions by means of simultaneous national expeditions from this country and from Germany, and the public will soon begin to ask where the Antarctic regions may be and why people wish to go there.

The forerunners of the inquiring public have hitherto been obliged to cull such information as may be obtainable by the tedious process of consulting the records of original voyages which have been "out of print" for a generation at least; but in 1898 Dr. Karl Fricker came to their aid by producing his admirable compilation, "Antarktis," the introductory volume of Kirchhoff and Fitzner's "Bibliothek der Länderkunde." Of this book it is impossible to speak too highly, and we must congratulate the editors and publishers of the series on their choice of a beginning. We must congratulate the English publishers also on having the courage to show the British public how much better the results of British pluck and enterprise are appreciated in Germany than at home. We know nothing less pleasant to contemplate with regard to the long Antarctic record than the apathy of the British public and publishers alike to the pioneer work of Cook, the public-spirited enterprise of the Enderbys, and the great achievements of Ross. The fact that the account of Ross's Antarctic voyage has never appeared in a popular edition is a mystery in the face of the frequent inquiries for that delightful book.

Dr. Fricker passes lightly over the early history of the Antarctic regions, not mentioning, we may note, Rainaud's excellent historical summary, "Le Continent Austral," in which the myth of the Great South Land is traced to its source. He takes up the work of Cook in the eighteenth century, of the Russian expedition under Bellingshausen, of Weddell, Biscoe, Balleny and the other sealers sent out by Messrs. Enderby Brothers, and deals in a thoroughly satisfactory manner with the simultaneous expeditions at the dawn of the Victorian era, when the French under Dumont d'Urville, the Americans under Wilkes and the British under Ross competed in the investigation of the south polar seas. Probably it was wise to pass lightly over the acrid controversy between Ross and Wilkes, although the English reader might have liked to see how such Homeric heroes assailed each other in the pages of the *Athenaeum* half a century ago.

The history of recent voyages stops with the trip of the *Antarctic* to Victoria Land in 1895. This was inevitable in the case of Dr. Fricker's German edition; but the translator might have endeavoured to convey, in a supplementary chapter, some idea of the great results which have been achieved since the first publication. It would only have been fair to the author to have given him the opportunity of revising his section on Bouvet Island, with which the detailed description of the various known lands of the Antarctic regions commences. The translator might at least have added a note to let the reader know that this interesting group, which was sought in vain by Cook and by Ross, was re-discovered by the *Valdivia* on November 25, 1898, during the first scientific voyage conducted by Germans to the edge of the Antarctic (see NATURE, vol. lx. p. 114).

---

[1] "The Antarctic Regions," by Dr. Karl Fricker. Pp. xii + 292. Maps and Plates. (London: Swan Sonnenschein and Co., Ltd., 1900.)

"Through the First Antarctic Night, 1898–99. A Narrative of the Voyage of the *Belgica* among newly-discovered lands and over an unknown sea about the South Pole." By Frederick A. Cook, M.D., Surgeon and Anthropologist of the Belgian Antarctic Expedition. Illustrated. Pp. xxiv + 478. (London: William Heinemann, 1900.)

The description of the various portions of land seen by Antarctic explorers is well done, and the critical remarks of the author appear to be judicious and likely to be of service to subsequent expeditions. Then follow accounts of the ice-conditions, on which Dr. Fricker has made himself an authority, climate and life. The book ends with a chapter on the future of Antarctic exploration, excellent when it was written, but now happily out of date.

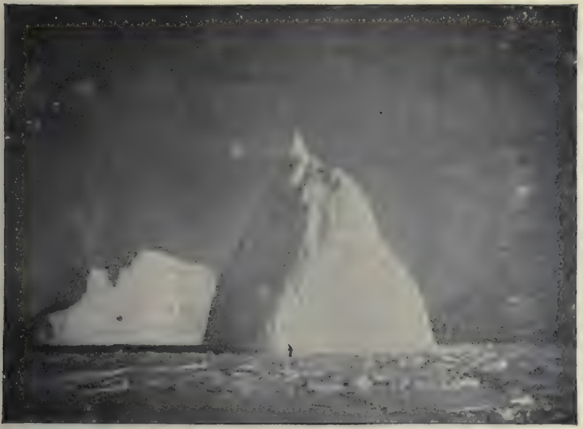

Fig. 1.—Curious weather-worn iceberg (300 feet high). (From Dr. Cook's "First Antarctic Night.")

Mr. A. Sonnenschein has translated the book very well indeed from the literary point of view. We could scarcely have believed it possible that a translation could be made so literal, and yet so free from constraint, as this one is. Still a scientific man cannot help noticing some slips in the rendering of technical expressions, and it may prove useful to the general reader to correct some of these. On p. 104, line 32, the translator interpolates "Mount" before "Erebus," not noticing that the author refers to the temporary position of the ship which was the mountain's godmother; similarly, on p. 117, the objectionable word "insects" is introduced after "coral" without Dr. Fricker's authority. On p. 120 "the lower parallel" scarcely conveys the idea "a great-circle course" which the author expressed. In several places the geological *dip* of rocks is rendered by *slope*, a totally different thing. On p. 175 "layers of secondary formation" suggests Mesozoic rocks, but drift, without regard to the geological character of the stones, is the true meaning. On p. 176 "precipitate rock" should be "sedimentary rock." In several places the word *schären* is translated "dunes," but it really refers to skerries or rocky islets like those of the Skärgård of Sweden. The phrase "relative moisture" is used throughout instead of the familiar "relative humidity." On p. 248 the translator suggests the use of the German word *firn* in English; but it seems to us that the French equivalent *névé* has received too general currency to be displaced from English writings. On p. 261 the word "Translator" has been inadvertently added to one of the author's footnotes.

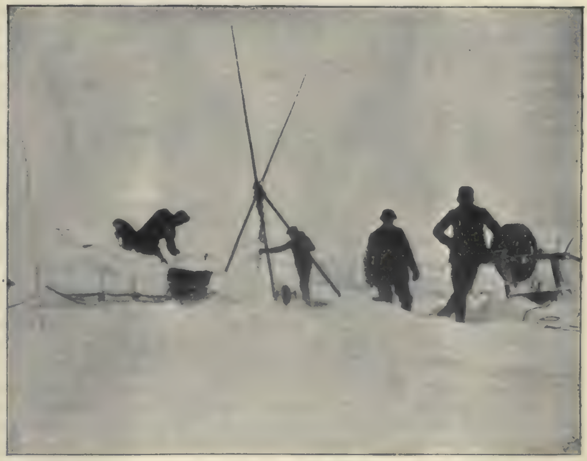

Fig. 2.—Making soundings. (From Dr. Cook's "First Antarctic Night.")

The editorial note prefixed to the English edition is not very satisfactory. It is gratifying news, which we have not seen before, that Belgium is actively fitting out an expedition for Antarctic exploration; but the statement that a Belgian expedition was sent out in 1897 should have been supplemented by the fact that it returned in 1899 with rich results. The *Valdivia* expedition is not noticed, although Mr. Borchgrevink's return properly finds a place. It would have been useful if the numerous recent papers on Antarctic exploration in English had been added to the bibliography, and if the efforts of Sir Clements Markham and the councils of the Royal Society and the Royal Geographical Society in promoting the British Antarctic Expedition had been specifically referred to.

Dr. Cook is the first of the staff of the *Belgica* to place his experiences on record in book form, and his description is intended for the general rather than the scientific reader. Its great value lies in the frankness with which the subjective side of exploration in the polar regions is dealt with, and in the professional observations on the health of the explorers. It will be remembered that the *Belgica*, after surveying part of the coasts of the channel which continues Bransfield Strait to the south between 64° and 65° S., sailed west and south, and wintered in the Antarctic pack, where for thirteen months the ship was fast in the ice. The claims as to geographical discovery, and the results of the scientific observations, may be left for discussion when the official report of the expedition is published. Dr. Cook says very little about the leader, M. de Gerlache, whose resolution to push as far as possible to the south does not seem to have met with the approval of his subordinates, and it is noticeable that de Gerlache's portrait is not given in the admirable series showing the officers and scientific staff before and after their experiences.

The preliminaries of the expedition when one might almost think time was wasted in Tierra del Fuego, are described in considerable detail; but the interest of the reader will be mainly attracted by the description of the first winter night (a night of seventy days) ever lived through by human beings in the Antarctic regions. It is described with a restrained realism that suggests many thoughts. We do not admire the author's style in such a passage as—"Even the sailors cannot resist the temptation to stand still and drink, with awe-inspiring amazement, the strange wine of action which hangs over the mysterious whiteness of the new world of ice"; but when he comes to deal with the details of every-day monotony in the narrow limits of the lonely ship, the narrative acquires an intensity of interest which the simplest and most correct expression could hardly increase. The efforts of the scientific staff to carry on observations in most unfavourable conditions deserve the greatest praise.

Dr. Cook attributes the terrible depression of spirits and the circulatory troubles which affected every one on board the *Belgica* to the absence of sunlight and the monotony of the food. He never mentions scurvy; but the symptoms described read not unlike the incipient stages of that disease. With regard to food, he raises a strong protest against essences and "artificial" foods of every kind. However nourishing these may be, their softness and want of flavour excite repulsion. Something with a taste, and tough enough for the teeth to have some work, was what the officers of the *Belgica* sighed for. Of all the foods on board, the Norwegian *Fiskeballar*, or "Fiskabolla," as it is written, were the objects of the heartiest detestation. Either the supply must have been of inferior quality or the abundance produced disgust, for only a few weeks ago we heard a person of intelligence declare spontaneously, on first tasting this delicacy, that with a supply of fiskeballar he could face a polar winter with equanimity. Sugar and milk ran short, and their loss was very severely felt. The experience of the *Belgica* should be very carefully considered by those responsible for victualling the new Antarctic expeditions, and compared with that of the *Fram*. Dr. Cook, by the way, throws doubt on the perfect health and general serenity of Dr. Nansen's expedition; but it appears possible that with a small company of one nationality, personally selected by the leader, and living together, the chance of harmony is greater than with a larger number divided into cabin and forecastle, composed of five nationalities, and speaking as many languages.

Both the books which we have brought together in this review are good, splendidly illustrated, and full of interest; but each would have been better of careful revision. Dr. Cook is unhappy with his proper names; we note *Grand* (for Gand), *Recluse* (for Reclus), Bismark, Monacho, Bellany (for Balleny), Jessup (for Jesup), and there is also carbon diolide, all of which are wrong. In both works the comparison of temperatures on the centigrade and Fahrenheit scales is sometimes at fault, and in one between the hours of 4 a.m. on Sunday and 8 a.m. on Monday several gentlemen succeeded in obtaining thirty-six hours of continuous sleep.

HUGH ROBERT MILL.

## NOTES.

LORD KELVIN proposes to give a valedictory address to the London Mathematical Society on November 8. The subject will be "The Transmission of Force through a Solid."

THINGS scientific are beginning to move in Egypt a little. A notice has been published in the official journal that on and after September 1 universal time will be adopted in Egypt, and the noonday signal given at mean noon of the 30th Meridian East of Greenwich, *i.e.* East European time. The Ports and Lights Administration have also notified that the time balls at Alexandria and Port Said will on and after October 1 be dropped according to the same time, and not local time as heretofore. At present these time balls are dropped by local arrangements, but before the end of the year the midday signal ball at each place will be dropped automatically by electric signal from Abbassia Observatory. Regarding meteorology, there are now eight stations between Alexandria and Khartum forwarding daily telegraphic weather reports, and these will be increased shortly. Abbassia has now a complete self-registering equipment, and hourly observations for 1900 will be published.

MR. J. S. BUDGETT, of Trinity College, Cambridge, who, it will be remembered, accompanied Mr. Graham Kerr on his journey in search of *Lepidosiren*, and who last year spent several months investigating the zoology of the Gambia region, has just returned to England from a second expedition to that river. Mr. Budgett's main object was to obtain material for studying the development of the Crossopterygian fish *Polypterus*. In his first expedition he obtained eggs and larvæ which were said to be those of this fish, but which, as it turned out, belonged apparently to a Teleost. Mr. Budgett has in his recent expedition failed to obtain the Polypterus material, but he is to a certain extent compensated for this by having obtained a mass of other embryological material which appears to be of great interest. Amongst this is a practically complete series of eggs and larvæ of the Dipnoan *Protopterus* whose developmental history had hitherto remained quite unknown. It is an interesting fact that the developmental stages of all three surviving members of the important group Dipnoi—*Ceratodus*, *Lepidosiren* and *Protopterus*, belonging to Queensland, South America and Africa respectively—owe their discovery and first observation to workers of the Cambridge school of Zoology.

AT the meeting of the Röntgen Society on November 1, Dr. J. B. Macintyre will deliver his presidential address.

LIEUT. C. LECOINTE, who was second in command of the Belgian Antarctic Expedition, has been appointed director of the astronomical work at Brussels Observatory, in succession to M. Lagrange, retired.

A REUTER correspondent at Friedrichshafen describes another ascent made with Count Zeppelin's air-ship on October 17. The balloon remained for three-quarters of an hour at an elevation of 600 metres, and, after carrying out a number of successful steering manœuvres, alighted safely on the lake shortly before 6 o'clock, half a mile from Manzell. Herr Eugen Wolf, who took part in the ascent, has given the following account of his experience:—"The trial lasted an hour and twenty minutes. The start upwards was first-rate. The air-ship moved at an almost unvaried height of 300 metres and went against the wind. All the steering tests proved the efficacy of the new gear, and the air-ship satisfactorily answered the movements of the steering apparatus. The horizontal stability of the vessel was wonderful. Any list was easily counteracted by shifting the sliding weight. The speed of the air-ship was such that, when going against the wind, it outstripped the motor boats on the lake. In still air its own speed was at least eight metres per second. We descended at full speed in the direction of the air-ship's shed rather faster than we expected, owing to an as yet unexplained escape of the whole of the gas in one of the balloons in the forward part of the ship. No damage of any importance was sustained in the descent. The King and Queen of Württemberg and Princess Maria Theresa of Bavaria watched the trial on private steamers."

SIR HENRY DYKE ACLAND, whose death we recorded last week will probably be remembered more on account of the influence he exerted on behalf of scientific education at Oxford than for his contributions to natural knowledge. He was born in 1815, and graduated in medicine in the University of Oxford in 1846, having previously been appointed Lee's Reader in Anatomy. He became Radcliffe Librarian in 1851, and Regius Professor of Medicine in 1857, which post he held until the year 1894. He was a member of the General Medical Council from 1854 to 1874, and president in the years 1874–1887, when Sir Richard Quain succeeded him. Referring to his work on the Council, the *Lancet* says it was invaluable, and as he was likewise a member of the Medical Education Committee of the Hebdomadal Council of the University of Oxford, his influence on the scope and direction of the course of studies of a medical student was very great indeed, and was invariably directed towards the enlargement of the scope of scientific training. Not only did he use his influence for the good of the medical profession in his own country, but he extended his interests to foreign countries, and in 1879 sent an eloquent and encouraging letter to the authorities of the Johns Hopkins University, urging his readers to higher things and to the raising of the standard of medical education. He always placed the greatest stress upon general culture as a necessary qualification for the successful medical man, and being himself of very wide interests and a man of science, displayed an excellent example of a scientific and scholarly physician. In 1869 he was appointed a member of the Commission to inquire into the sanitary laws of England and Wales, and did valuable work in connection with it. He was the author of several works on medical and scientific subjects, including an important memoir on the visitation of cholera in Oxford in 1854, and another on village health and village life written in 1884 for the International Health Exhibition.

A LITTLE more than a year ago the attention of the Council of the Manchester Literary and Philosophical Society was directed to the fact that Dalton's tomb in Ardwick cemetery, Manchester, was in a very bad condition, owing to neglect. A committee was appointed to take steps to put the monument in a thorough state of repair, and there was no difficulty in obtaining subscriptions for this purpose. A full-page illustration of the tomb in its restored condition appears in the latest number of the *Memoirs and Proceedings* of the Society.

REFERRING to the age of the big trees of California, Prof. C. E. Bessey records in *Science* that he once counted with much care the rings of growth of the tree of which the stump constitutes the floor of the so-called dancing pavilion. This count was made from circumference to centre, and every ring in all that distance was counted, no estimates or guesses being made. The result was that 1147 rings were counted, and accordingly it is safe to say that this tree, which was fully 24 or 25 feet in diameter, and considerably more than 300 feet in height, acquired these dimensions in eleven hundred and forty-seven years. Prof. Bessey doubts whether any of the existing trees approach the age of two thousand years.

A DESCRIPTION of the condition of gases, materials and food in a mine which had been tightly closed for fifteen months was given by Mr. F. G. Meachem at the recent meeting of the Institution of Mining Engineers. When the mine was reopened, the air was analysed and was found to consist of 84 per cent. of nitrogen, 12 per cent. of fire-damp, and 4 per cent. of carbon dioxide. The gases were greatly compressed, and it is estimated that about 1,500,000 cubic feet escaped from the first bore hole in twenty-four hours. When the mine was entered, it was found that the gases had had no deleterious effect upon the food, or the materials left in the mine; in fact, everything left in the mine was found practically undamaged. Bread had become as dry as biscuit, cooked bacon was as fresh as when left, and water in the horses' tubs had not evaporated, although surrounded by perfectly dry coal-dust. Previous to the fire, oatmeal was supplied to men working in hot places to mix with their drinking-water, and this was found to be as sweet as when sent down the pit. The rails and ropes were not rusted. Men's clothing was dry, and in practically the same condition as when left. In the stables, the chaff was unimpaired, and the horses readily ate it. The timber in the pit did not seem to have undergone any change whatever. In the three months that had elapsed since the reopening of the mine, greater decay had taken place than during the fifteen months that the pit was closed.

MALARIA is not the only disease which is propagated by mosquitoes. In the *Atti dei Lincei*, ix. 5, Prof. Grassi and G. Noè describe observations on the transmission of the filariæ of the blood by mosquito bites. The same species, *Anopheles claviger*, which is mainly responsible for the dissemination of malaria, also plays the part of host to *Filaria immitis*. The present investigation deals with the mode of exit adopted by the filariæ in passing from the mosquito to the punctured animal, and it would appear that the parasites make their escape by means of a rupture in the integument of the labium. In the succeeding part of the same journal, Prof. Grassi describes experiments carried out by a committee with the assistance both of the Italian Government and of the Mediterranean Railway Company, with a view to the prevention and cure of malaria in infected districts. The experiments were carried out in the plains about Pæstum, which have long been known as a hot-bed of malaria ("malaricissima" is the epithet Grassi applies to the region), and fell into two categories, namely, cure of the disease by the use of quinine, and protection from the bites of *Anopheles claviger* by the use of wire gauze as a covering for windows, doors and even chimneys of houses, the inhabitants of which were required to remain indoors from before sunset till after sunrise, or to go about covered with veils at night. By thus preventing mosquito bites, it was found that the malarial regions could be safely inhabited even at the season when the fever was at its height, and under such conditions the district might be made as healthy as any part of Italy.

IN opening the recent International Aeronautical Congress at the Meudon Observatory, the president, M. Janssen, rapidly and very eloquently reviewed the most important points of the progress made since the meeting of the last congress held at Paris in 1889. During the interval, progress has been considerable in all directions, and new and important questions have been dealt with. The military authorities of several of the European countries have rendered much assistance in allowing their balloons and requisite appliances to be used in scientific investigations. In Germany alone no less than seventy-five ascents have been made during the last five years, the results of which have recently been discussed in a valuable work by MM. Assmann and Berson. Since the last congress in 1889, M. Le Monnier's idea of employing unmanned balloons has been realised; the success of these ascents and the results obtained by their means, notably in the investigations of MM. Violle and Cailletet, have given rise to the creation of the International Aeronautical Committee, which recently met in Paris under the presidency of Dr. Hergesell. M. Janssen also referred to the important results obtained from kite observations, especially by Mr. Rotch and M. L. Teisserenc de Bort. At the Berlin Meteorological Office a new service has been established for experiments, both with kites and balloons. The use of balloons for astronomical observations was also discussed, and recommended for observing the Leonid showers in November next. This method was successfully used under M. Janssen's directions by M. Hausky, in 1898, and was adopted by other countries in the following year.

The U.S. pilot chart of the North Atlantic Ocean for October shows the track of the Galveston hurricane. The storm was first noted to the east of Martinique on August 30. Next morning its centre passed slightly to the northward of Antigua, where the barometer fell to 29·84 inches; it traversed the southern portion of Haiti on September 1, and reached the southern part of Cuba on the 3rd. The barometric depression, which had been quite shallow, began to deepen over western Cuba, where the barometer read 29·79 inches on September 5. To the west of southern Florida the storm increased rapidly in area and strength, a reading of 28·10 inches and gales of hurricane force being noted on September 7 in lat. 26° 40′ N., long. 90° W. The storm-centre passed slightly southward of Galveston on September 8. The destruction of life and property at and near this city was unprecedented in the history of West India hurricanes. The strength of the storm decreased rapidly to the northward of Galveston, again increasing in the region of the Great Lakes, Newfoundland and the Grand Banks, where it attained great violence, force 12 being frequently reported. The storm moved to the north of the 60th parallel in about 20° W. on September 16. The recurving so far westward, long. 98°, is quite unusual. Before recurvature, the storm moved in a W.N.W. direction, and after recurving it took an E.N.E. course, its progressive movement increasing greatly in velocity.

Naturalists will read with much interest a paper by Mr. R. Hall in the October number of the *Zoologist*, describing his experiences among the elephant seals of Kerguelen Island. The visit took place during the winter of 1897–98, when Mr. Hall found these huge animals in great numbers. He believes that they arrive in August on the island, whence, after breeding, they depart in February or March. A large male may measure as much as 20½ feet in length, and the weight of many of the animals is estimated at between two and six tons. The finest herd seen included a couple of dozen males averaging about 19 feet in length. In disposition these seals are sluggish and peaceful, although when attacked many of them will show fight. On several days from sixty to seventy were killed, but forty *per diem* was considered a good average. It is to be hoped that steps will be taken by Government to prevent the extermination of these remarkable seals. Mr. Hall gives a characteristic photograph of a group on shore. In the same journal, Mr. E. Selous brings to a close his diary of the habits of the thicknee, or great plover (*Œdicnemus crepitans*), in the course of which he notices that these birds indulge in dances comparable to those so graphically described by Mr. W. H. Hudson in the case of an Argentine plover.

The latest issue (vol. xiii. pt. 2), of the *Journal* of the College of Science at Tokyo, contains a coloured plate and description of a gigantic and gorgeously coloured medusiform hydroid recently captured in deep water off Misaki. It is identified by its describer, Mr. Miyajima, with a form obtained in Japanese waters during the *Challenger* expedition, and named by Prof. Allman *Monocaulus imperator*, the generic title being now changed to Branchiocerianthus. There are, however, certain differences from the type-specimen of the latter, and other examples are much needed in order to determine the value of these variations.

The Yorkshire College, Leeds, together with the conjoint Agricultural Council of the East and West Ridings, have just published a pamphlet on sheep-breeding experiments in the county, forming No. 13 of their series. It is a common custom in Yorkshire to cross ordinary ewes with pedigree rams of other breeds; and the object of the experiments has been to ascertain whether such crosses are profitable, and which are the best. The results are tabulated in the pamphlet.

The October number of the *Biologisches Centrablatt* includes a paper by Herr Stempell on the formation and growth of the shells of molluscs; and another, by Herr Wesenberg-Lund, on the relation between the fresh-water plankton and the specific gravity of the water in which it occurs.

We have received from the Trustees of the Indian Museum, Calcutta, a fasciculus of the "Illustrations of the Zoology of the R.I.M.S. *Investigator*," containing the plates to Fishes (Part vii.) and Crustacea (Part viii.), and also the index to Part i. (1892–1900).

The U.S. Department of Agriculture, in *Bulletin* No. 24, has just issued a list of works on North American entomology, compiled by Mr. N. Banks. With the exception of a few dealing with the general subjects, the various memoirs are catalogued under the headings of the different groups to which they refer.

We have received from Prof. Jamshedje Edalji a paper on "Reciprocally related figures and the principle of continuity," which is remarkable as a collection of exercises in polar reciprocation. It contains reciprocal theorems corresponding to the properties of the circle contained in Euclid's Third Book, as also to many of the exercises in Todhunter's Euclid.

In the *Berichte der naturforschenden Gesellschaft* (Freiburg i. Br), Dr. Otto Berg discusses the significance of kathodic rays in connection with the mechanism of discharge. In connection with the heating effects produced when kathodic rays fall on a solid body, experiments with a thermo-element show that (1) for given potential the heat produced is proportional to the quantity of electricity carried over; (2) the ratio of the quantities of heat and electricity decreases as the potential increases. The same journal also contains a paper by Dr. F. Himstedt on observations with Becquerel and Röntgen rays. Dr. Himstedt has observed no action of radium on a coherer, but has found a noticeable reduction of resistance of a selenium cell due to these rays. A similar diminution of resistance amounting to as much as 50 per cent. is produced when Röntgen rays fall on a selenium cell, and this effect might be conveniently used to measure the intensity of Röntgen rays. The same action is also produced by ultra-violet, but not, according to Dr. Himstedt's experience, by ultra-red light.

The *American Naturalist* states that the discontinuance of the Italian scientific journal *Erythea* has been immediately followed by the reappearance of *Zoe*, a journal of very much the same scope, after a suspension of several years.

An interesting report is printed by the U.S. Department of Agriculture (Division of Vegetable Physiology and Pathology) by Mr. Hermann von Schrenk, on two diseases of the red cedar (*Juniperus virginiana*), caused by the attacks of two parasitic fungi, *Polyporus juniperinus* and *P. corneus*, the former new to science. The paper is copiously illustrated by seven plates.

Prof. F. Péchoutre, of the Lycée Buffon, Paris, contributes to the *Revue générale des Sciences* (for September 30) a very interesting epitome of recent researches in vegetable cytology and the process of impregnation in flowering plants. A very useful summary is given of all the most important papers—and they have been very numerous—published on the Continent, in England, in Japan, and in America, during the last three years, under the following heads:—Centrosomes and blepharoplasts; Chromatic Reduction; Centrosomes and kinetic centres; the influence of organic substances on the action of nitrifying microbes; the Antherozoids of Angiosperms and double impregnation; the phenomenon of *Xenia* and the hybrid impregnation of the endosperm. Under the last heading the observations of De Vries and Correns are referred to, but not the most recent ones by Webber; and several of the sections are illustrated by excellent wood-cuts.

MESSRS. C. BAKER, of High Holborn, send us their illustrated catalogue of microscopes and accessories, and stains, reagents, &c., for use in pathological and bacteriological research, including necessaries for the study of tropical diseases and examination of blood. The slide-lending department existing in connection with this firm appears to meet a distinct want.

THE Hampstead Astronomical and Scientific Society encourages interest in natural knowledge by popular lectures and instructive papers on scientific subjects. A course of six lectures upon the astronomy of the spectroscope and photographic camera will be delivered on Monday evenings at the Hampstead Library by Mr. P. E. Vizard, commencing on November 12. The programme of papers to be read at the meetings is an attractive one, and should be the means of increasing the membership of the Society.

FOUR public lectures will be given in the library of the Sanitary Institute under the auspices of the Childhood Society, which exists for the scientific study of the mental and physical conditions of children. The lectures will be as follows: "Treatment of Feeble-Minded Children in Asylums," by Rev. T. W. Sharpe, C.B.; "The Training of Teachers," by Prof. W. H. Woodward; "Physiology for Teachers," by Prof. C. S. Sherrington; "Causes of Failure in the Health of School Girls," by Mrs. D. Colman.

THE list of announcements of the firm of Gebrüder Borntraeger, Berlin, has just reached us, and is as follows:—"Sammlung geologischer Führer": vol. v. Elsass (Vogesen), by Drs. Benecke, Bücking, van Werveke and Schumacher; vol. vi. Riesengebirge, by Dr. Gürich; vol. vii. Schonen (Schweden), by Dr. Hennig; "Lehre von den Erzlagerstätten," by Prof. R. Beck (Part i.); "Flora der Deutschen Schutzgebiete in der Südsee," by Drs. C. Lauterbach and C. Schumann; "Werden und Vergehen," by Carus Sterne, fourth edition, vol. ii.

THE British South Africa Company has issued a pamphlet on the rubber industry of its territories. The rubber-producing plants of the territory are described as being mostly gigantic creepers belonging to the natural order Apocynaceæ. The pamphlet is chiefly occupied with hints on the administrative policy desirable for the protection and encouragement of the industry. Apparently no serious effort has yet been made either to ascertain the rubber-producing value of the native trees and shrubs, or to encourage the cultivation of those species which are found to be most valuable.

THE edition of Darwin's "Origin of Species," just published by Mr. John Murray for half-a-crown, is the cheapest scientific book we have had before us for many a day. The volume is clearly printed, has more than seven hundred pages, and a collotype portrait of Darwin appears as a frontispiece. The first edition of the work was published on November 24, 1859, so the copyright will shortly expire, and probably other editions will be issued by various publishers, but the book which Mr. Murray has brought out will be able to hold its own against all that follow it. If there is a person who claims to be a naturalist, or even to have an interest in natural history, and does not possess a copy of Darwin's immortal work, he should make haste to add the new book to his library.

THE Cambridge Scientific Instrument Company have issued a list of apparatus designed and used by Prof. Ewing, F.R.S., for the teaching of mechanics in engineering laboratories, and now manufactured in their works. Several of these pieces of apparatus relate to experiments on the elasticity of materials, and to measurements of the moduluses of elasticity, by various methods. Amongst these are the latest forms of Prof. Ewing's microscope extensometer. The remaining instruments and devices are designed to enable students to make quantitative experiments in mechanics. The importance of such mechanical laboratory work, carried out by the students themselves, as a supplement to their study of theoretical mechanics by books or lectures, is now generally recognised. Well-made instruments such as are supplied by the Cambridge Company are essential to ensure accurate work by advanced students.

IN the last number of the *Berichte*, E. Fischer gives an account of further investigations on the division of racemic amido-acids into their optical components. He found previously that by replacing hydrogen in the amido-group in these acids by a benzoyl group, compounds of much more strongly marked acid characters are produced, which are capable of forming well crystallised salts with bases. By crystallising such salts of the active alkaloids, strychnine, brucine, cinchonine, the amido-acids in the form of their benzoyl derivatives have been divided. Alanine, aspartic acid and glutaminic acid were the first to be resolved by this method, and these have now been followed by leucine, amidocaproic acid, phenylalanine and α-amidobutyric acid.

IN the same journal, v. Baeyer and Villiger discuss the action of permanganate on hydrogen peroxide and assail the views of Berthelot and Bach on the existence of oxides of hydrogen higher than the dioxide. Berthelot found that at a low temperature permanganate is decolourised without evolution of oxygen, which he ascribes to the formation of hydrogen trioxide ($H_2O_3$). The authors, on the other hand, find that at $-16°$, though more slowly, the same volume of oxygen is evolved as at the ordinary temperature. Bach concluded that, as an excess of oxygen above the calculated quantity was evolved with permanganate, "Caro's acid" (hydrogen peroxide in sulphuric acid) contained hydrogen tetroxide. The authors find this observation correct, but the interpretation at fault. They ascribe the decomposition to the catalytic decomposition of Caro's acid, due to the presence of manganous sulphate. Of the nature of the process which occurs when hydrogen peroxide and permanganate react, the authors bring facts in support of the view of Weltzien and M. Traube, who consider that the permanganate oxidises the hydrogen of the peroxide, thereby liberating the oxygen of the latter, and not that the free oxygen is made up of oxygen atoms derived from both peroxide and permanganate.

THE additions to the Zoological Society's Gardens during the past week include a Patas Monkey (*Cercopithecus patas*) from West Africa, presented by Mrs. Creighton Hall; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Cecil T. Reaney; a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. Anthony J. Smith; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. G. H. Jalland; two Muscat Gazelles (*Gazella muscatensis*) from Arabia, an Indian Desert Fox (*Canis leucopus*) from India, presented by Mr. P. Z. Cox; a Bonnet Monkey (*Macacus sinicus*) from India, a Sooty Mangabey (*Cercocebus fuliginosus*) from West Africa, a Ruffled Lemur (*Lemur varius*), a Black-headed Lemur (*Lemur brunneus*) from Madagascar, a Short-tailed Wallaby (*Macropus brachyurus*), a Great Kangaroo (*Macropus giganteus*), four Brown's Parrakeets (*Platycercus browni*) from Australia, a Blue-necked Cassowary (*Casuarius intensus*), two One-Wattled Cassowaries (*Casuarius uniappendiculatus*) from New Guinea, seventeen Speckled Terrapins (*Clemmys guttata*), three Painted Terrapins (*Chrysemys picta*), ten Alligator Terrapins (*Chelydra serpentina*) from North America, an Elephantine Tortoise (*Testudo elephantina*) from the Aldabra Island, an Oldham's Terrapin (*Cyclemys dhor*) from the Malay Peninsula, a Missel Thrush (*Turdus viscivorus*), European, deposited.

## OUR ASTRONOMICAL COLUMN.

EPHEMERIS FOR OBSERVATIONS OF EROS:—

| 1900. | R.A.<br>h. m. s. | Decl.<br>° ′ ″ |
|---|---|---|
| Oct. 25 | 2 27 27·35 | +52 36 52·0 |
| 26 | 25 52·13 | 52 49 53·2 |
| 27 | 24 13·05 | 53 2 9·2 |

| Nov. 1 | 2 15 8·32 | +53 51 11·3 |

OPPOSITION OF EROS.—M. Loewy has distributed a fifth circular containing additional information intended to secure uniformity of observation among the many institutions which have now commenced their work of determining the parallax of Eros. It is advised that the positions relative to neighbouring stars be measured in rectangular co-ordinates, and also that the eleventh magnitude be adopted as the inferior limit of brightness for the comparison stars. For those undertaking photographic determinations, it is recommended—

(1) That on each plate there be made two exposures of different length, so that each star may be recorded by two images some twenty seconds of arc apart in declination. This procedure will fulfil the two functions of eliminating spurious stars, and of enabling two series of measures to be made on star-discs of very different diameters, so that the photographic spreading effect may be allowed for to some extent. For instruments of the type employed for the international chart (0·33 metre aperture), exposures of six and three minutes are recommended.

(2) On the plates especially for the planet's position, two exposures should also be made, one while the guiding star is accurately followed, the other keeping the planet on the cross wires, or if this be too difficult on account of its faintness, the guide star should be given a motion equal, and in the contrary direction to that of the planet. The result of these operations will be two images of Eros, one showing as a short faint line, the other as a circular patch. This is now known to be quite possible, as the planet has recently been photographed, October 4 and 6, both at Paris and Algiers, in three minutes, the magnitude being estimated at 10·5. Prof. Joly also states that with the 15-inch reflector at Dublin, images were obtained with exposures of six and two minutes.

Another list of comparison stars is provided, and the ephemeris extended to March 1901. The brightness of Eros is now slowly increasing, being 9·81 magnitude on October 29, reaching its maximum of 9·02 on December 18, and then decreasing to 10·48 in March at the close of the time of these special observations. M. Loewy asks all collaborating in the enterprise to forward regularly the successive progress made in the various sections.

NEW DOUBLE STARS.—In the *Astronomische Nachrichten* (Bd. 153, No. 3668), Mr. R. G. Aitken gives the particulars relating to 62 new double stars discovered by him with the 12-inch equatorial of the Lick Observatory. This list is supplementary to that previously published in *Astronomische Nachrichten*, No. 3635. Each star after discovery has been measured with the 36-inch telescope on at least one night; 39 of the pairs are under 2″ distance, 24 under 1″, and twelve under 0″·5. The list has been checked by comparison with Prof. Burnham's General Catalogue of Double Stars.

ASTRONOMICAL WORK AT DARAMONA OBSERVATORY.—We are in receipt of an interesting volume from Mr. W. E. Wilson, containing reprints of the astronomical and physical researches made at his observatory at Daramona, Westmeath, since 1892. Mr. Wilson started in 1871 with a 12-inch equatorial, by Grubb, but did little more with this instrument than lunar photography with wet plates and determinations of solar radiation. In 1881, however, he built the present large observatory attached to the house, and installed therein a new 24-inch silver-on-glass mirror of 10 feet 6 inches focus. The old 12-inch mounting proving too light for the extra load, it was replaced in 1892 by one of the best pattern with Grubb driving clock and electrical control. In 1889, an additional laboratory was added for the physical investigations which have formed so large a portion of the observer's programme.

The purely astronomical work with the 24-inch has practically been confined to the photography of star clusters and nebulæ. Very beautiful reproductions in collotype of some of these are included at the end of the volume.

The astrophysical portions deal with experimental investigations on the heat of the sun, absorption of heat in the solar atmospheres, thermal radiation of sun (both photosphere and spots) and electrical measurement of starlight.

## HISTORICAL ASPECTS OF THE DISCOVERY OF THE CIRCULATION OF THE BLOOD.[1]

THE discovery of the circulation of the blood by William Harvey is commonly regarded among scientific discoveries as eminent if not unique; and this in the judgment not of Englishmen only. My purpose to-day is to show that at any rate it was made against enormous difficulties.

To put this discovery in right perspective we must have some vision of the history of philosophy, science and medicine. Medicine, herein in contrast with Theology and Law, had its sources almost wholly in the Greeks; from them for good or evil it took its first scheme of thought; and in the schools of Hippocrates and of Alexandria it was based, more soundly, on natural history and anatomy. The noble figure of Galen, the first physiologist and the last of the great Greek physicians, portrayed for us by Dr. Payne in the Harveian Oration of 1896, stood eminent upon the brow of the abyss when, as if by some convulsion of nature, Medicine was overwhelmed for fifteen centuries. Galen practised the method of verification by experiment, first introduced perhaps by Archimedes, but after him it was lost till the time of Gilbert, Galileo and Harvey.

In the growth of societies small civilisations have been sacrificed to the formation of larger aggregates, whereby stable equilibrium may be attained for the highest ends. Perhaps because of her very freedom of thought Greece never became a nation. Even the Roman peace, bought as it was at the cost of learning and the arts, was but a mechanical peace. In the wilder regions of the empire the bodies but not the wills, of men were in subjugation, and even in Rome itself the sanction of patriotism was failing. Under the Frankish invasion the very traditions of learning and obedience seemed to be broken up. Then Europe was saved by the inspiration of the Christian religion which, entering as a new element into the ancient fabric of Roman empire, was now to hold men's service in heart and soul as well as in body; but to this end no mere mystic or personal religion could suffice; clothing itself with the political and ritual pride, and even with the mythology of the pagan empire, it inspired a new adoration; but it imposed upon men also a universal and elaborated creed. In the third century philosophy was born again in neo-platonism, the offspring of the coition of East and West in Alexandria, where all religions and all philosophies met. The world and the flesh were crucified that by the spirit man might enter into God. Pure in its ethical mood, neo-platonism, says Harnack, led surely to intellectual bankruptcy; the irruption of the barbarians was not altogether the cause of the eclipse of natural knowledge. Yet even then, as again and again, the genius of Aristotle came to save the human mind. Proclus, ascetic as he was, was also versed in Aristotle; he compelled the Eastern mysteries into peripatetic categories, and bequeathed a formal philosophy to the faith. Thus the first Scholastic period was fashioned, and the objects and methods of inquiry were determined for thirty generations. Rationalised dogma lived upon dialectic, and conflicted with mysticism; but logic, dogma and mysticism alike disdained experience. The Faith, then, was the first adversary of Copernicus, Galileo and Harvey.

It was the fortune of the Faith that, of all the treatises of Plato, the Timæus, the most fantastic and least scientific, should have survived to instruct the mediæval world; while those works of Aristotle which might have made for natural knowledge fell out of men's hands: moreover, the Categories and the "Interpretation" made for more than Aristotelian nominalism, and turned men's minds rather to rhetoric and dialectic than to natural science. Thus Plato's chimæra of the human microcosm, a reflection of his theory of the macrocosm, stood beside the Faith as the second great adversary of physiology.

The influence of authority, whereby Europe was to be welded together, penetrated into all human ideas. As was the authority of the Faith, so was that of Plato; and, in the second period of the Middle Ages, of the Arabian versions of Aristotle and Galen. It is not easy for us to realise a time when intellectual progress, which involves the successive abandonment of provisional syntheses, was unconceived; when truths were regarded as absolute; when reasons were not tested but counted; when even Averroists found final answers either in Aristotle or in Galen. Thus in the irony of things was Harvey withstood by the dogma of that Galen who, in his own day, had earnestly appealed from dogma to nature.

---

[1] Abstract of the Harveian Oration of 1900, delivered by Prof. Clifford Allbutt, F.R.S.

In the Isagoge of Porphyry is set forth distinctly a problem, which during the Middle Ages rent Western Europe asunder; a problem, says John of Salisbury, which engaged more of the time and passions of men than for the house of Cæsar to conquer and govern the world; a problem, indeed, which in our own day is not wholly resolved. This was the controversy of the Realists and Nominalists, first brought to a clear issue by William of Champeaux and Roscellinus respectively. Now Plato held ideas not as mere abstractions but as creative forces; and we shall see how potent was this function in mediæval thought. Every particular, every thing, was regarded by the realist as the product of universal matter and individual form. Now form might be regarded, and variously was regarded, as a shaping, determinative force or principle, pattern or mould, having a real existence apart from stuff; or, on the other hand, as an abstract principle or pattern having no existence but as a conception of the mind of the observer. And for the Realist, not individuals only, but genera and species also have their forms; either preexistent (*universalia ante rem*) or continuously evolved in the several acts of creation (*universalia in re*). For instance, the Church for the Realist is a thing apart from the wills of successive generations of individual men; Man has fallen, not only in many or all individual cases, but also as a kind—a kind having an independent existence; in the Sacraments again there may be a change of hypostasis without change in sensible matter. Now, if forms pre-exist (*ante rem*), the will of God must be predetermined; or if form be an immanent function acting in *re*, we are landed in pantheism. Thus Erigena, the brilliant prophet and protestant of the first period of the scholastic philosophy, was virtually a pantheist, as Spinoza was the last great realist. Aquinas, who determined the philosophy now ruling in Rome, brought about a compromise, which covers up rather than solves the difficulty. The problem, it is evident, was no hair-splitting; it dealt with the very nature and origin of being, and it agitated the minds of earnest men at a time of fervid and widespread enthusiasm for knowledge.

Now closely allied to the argument concerning universals was that concerning "matter and form." Whether the terms used were "form and matter," "force, energy or pneuma and matter," "soul, archæus or life and body," "determinative essence and determinate subsistence," "male principle and female element," "the potter and the clay of the potter"; or whether again they were "effect and cause," "nature and law," "being and becoming," the riddle lay in the contrast of the static and dynamic aspects of things; in the incessant formation of variable individuals in the eternal ocean of existence. Even Francis Bacon never got out of the tangle of Form, Cause and Law. It has been the temptation of philosophers of all times, and even of Harvey himself, than whom none had put better the conditions of scientific method, to suppose that by means of abstraction kinds may be apprehended; that thus they may get nearer to the inmost core of things; that by purging away the characters of individuals they may detect the essence and the cause of individuation; not perceiving that the content of notions is indeed in inverse proportion to their universality. We see this error continually to-day. For instance, we may discuss the causes of typhoid fever, and bewilder ourselves by forgetting that there is no such thing as typhoid fever, and that the only causes of a general notion are the psychological causes of its generation in the mind of the thinker at the time; that which is due to objective causes is of course not the notion, but the particular case—a very different affair.

Before motionless stuff—before the problem of the "primum mobile," even Harvey himself, when he had come to the end of his admirable experiments and began to indulge in contemplation, stood helpless. In his need for a motor for his machine he was not able to divest himself of the language nor even of the philosophy of his day. In his day he could not help regarding rest and motion as different things, and motion as a superadded quality. The motion he attributes, not to a property of the heart, but of the blood—to its "innate heat," which is as far as he could possibly have got. But, by way of explanation, he adds that the innate heat of the blood "is not fire, nor derived from fire"; nor is the blood occupied by a spirit, but is a spirit; it is also "celestial in nature, the soul, that which answers to the essence of the stars . . . is something analogous to heaven, the instrument of heaven." In denying that a spirit descends and stows itself in the blood or elsewhere, as an "extraneous inmate," he bravely says: "I cannot discover this spirit with my senses, nor any seat of it"; and yet, in the treatise "De Generatione," he propounds a theory of the impregnation of the female, not by any material from the male, but by the influence upon her of a "general immaterial idea"; which, even for his own time, was very substantial realism. The riddle which oppressed the great thinkers, from the Greeks to Lavoisier, was, then, the nature of the "Bildungstrieb"—of the "impetum faciens." What makes the ball to roll? Does heart move blood, or blood move heart? and, in either case, what bestows and perpetuates the motion? Telesius, the first of the brilliant band of natural philosophers in Italy of the sixteenth and seventeenth centuries, still sought this principle of nature in the "form" of the peripatetics. Gilbert regarded his magnetic force as "of the nature of soul, surpassing the soul of man." Galileo, although willing to conceive circular motion as perpetual, and even self-existent, was unable thus to conceive rectilineal motion. All these naturalists, including Harvey, and even Descartes, followed the mediæval world and Aristotle in deriving the source of motion directly from that of the spheres—from the quintessence (*vid.* Arist. De Coelo; and Met. xii.). Till Copernicus transfigured the cosmos, and Galileo and Newton carried terrestrial physics into the celestial worlds, the heavenly bodies were regarded as animated beings, themselves active, and, by propagation from sphere to sphere, animating all "sublunary" matter, wheels within wheels, even to its innermost particles.

Of the origin of energy we have not solved the riddle; we have given it up; but instead of finding its sources without we find them within. Harvey's contemporary, Francis Bacon, sagaciously guessed that heat is an expansive motion of particles; but he regarded heat and cold as two contrary principles. Almost in the same generation the brilliant John Mayow perceived a substance in the air "allied to saltpetre," which passed in and out of the blood by the way of the lungs or placenta. So innate heat gave way to phlogiston, and soon afterwards oxygen and the conservation of energy turned out to be the "form" "spirit," "essence," "primum mobile," "causa efficiens," "potentiality," and the rest of them; so by Lavoisier, a vast pile of metaphysics was blown into the air. But to kill a strong theory outright takes many a generation; realism, shaken by Abelard, and scotched by Hales and Ockham, not only survived to mislead Harvey, but it stretches its withered hand over us still—in the nursery, in the schoolroom, in the university, and in the great arguments of life.[1]

As strong as realism was a third adversity—the pride of the human mind. The asceticism derived from the East, disdainful of carnal things, brought the dualism of matter and spirit into monstrous eminence; and in respect of medicine, in a few generations it turned the cleanest people in the world into the most filthy.[2] Almost to this day the mechanical arts, presumably concerned with lower categories, have been regarded as base; and the crafts, even of the laboratory, as unworthy of great souls.

Anatomy had to labour also against both ecclesiastical and popular antipathy; chemistry and mechanics were gross pursuits unless endowed with the perilous distinction of alchemy and sorcery. Unfortunately, this charge upon the dignity of man was made heavier rather than lighter by Petrarch and the humanists of the Renascence; and in Oxford of the seventeenth century we find that Boyle was bantered by his friends as one "given up to base and mechanical pursuits." In a certain important respect medicine suffered greatly from this prejudice. It is obvious that, speaking generally, medicine would find its most positive and direct control in those diseases and in those therapeutical experiments which are manifest on the outside of the body. Yet surgery fell under the proscription of a handicraft, and as such was eliminated from the colleges of physicians both in London and Paris. Thus the genuine work of such men as Paré and Gale were without influence upon medicine, and thus it came about that Francis Bacon said of the physicians of Harvey's day that they saw things from afar off, as if from a high tower. From Erasistratus to Celsus, physicians practised medicine as one art. Galen taught, not the simplicity, but the unity of medicine; and Littré points out that this unity is consistent in the Hippocratic writings. Surgery, by virtue of its imperative methods, was kept clear of philosophy on the one hand and of humanism on the other. Fortunately for Harvey, his master, Fabricius, was as great a surgeon as anatomist; and such was Fallopius. Thus it was that medicine, at the end of the Middle Ages, had not recovered the standard of Alexandria. And against this adversity, also, had the founder of physiology to contend.

---

[1] The readers of NATURE know how effectively this mischievous survival has been attacked recently by Prof. Perry, Mr. Heaviside and other contributors. But even greater men, whose blows still resound through the centuries, have attacked it in vain.

[2] Those curious in such things will notice that the mediævalising clergy of our own day have discarded in their persons that fair linen which in their fathers was the emblem and example of cleanliness.

Happily the Arabian scholastic philosophy took its root in Alexandria when neo-platonism had veered towards Aristotle, and it was therefore more uniformly peripatetic than the Christian scholasticism. It is one of the signs of the greatness of Aristotle that, thus garbled and glossed, his power made itself felt in the thirteenth century, chiefly by the great Franciscans Alexander Hales, Roger Bacon, and William Ockham—Roger Bacon, whom we may call the first of the natural philosophers of the West. This former renascence determined the second period of the Middle Ages: the period distinguished by the Arabian version of Aristotle, by a check to the chimæras of realism, by some liberty of secular knowledge—for even bishops came out of the school of Toledo—and again by the coming of the Friars, whose influence upon the thought of the Middle Ages was a curious proof that, as all ways are said to lead to Rome, so all systems of thought, in spite of the thinkers, led to natural science. The logic and rhetoric of the Dominicans, by their rationalism, defined, and in defining restricted, the dominion of the Faith. Men got used to reason, and made a language for thought. And in the history of the unlearned Friars Minors we find, as elsewhere in history, that mysticism is more favourable to natural knowledge than the passionate dogmatism of Clairvaux or the dogmatic rationalism of St. Thomas. The Victorians, as Gerson after them, despised reason rather than feared it; mysticism makes for individual religion, as in Glisson and Newton, rather than for the Church. Hence it may have been that independent thinkers, like Hales and Bacon and Ockham, entered the Franciscan Order. The former renascence bred also a more tolerant spirit. Albert of Cologne owed as much to Avicenna as St. Thomas to Averroes: sages technically damnable, yet "mighty spirits," worthy of reverence. Dante put in hell, but on green meadows, in an open place, lofty and luminous, not only Aristotle, Plato and Socrates, but also Euclid, Ptolemy, Hippocrates, Avicenna, Galen and "Averroes who made the great commentary." Universities were founded in France, England and Italy. But the natural science which made the second renascence irresistible was absent from the former; and at the end of the century a reaction set in. During the two following centuries in Spain freedom of thought was crushed out by the Church; but in the conflagration of books of philosophy, medical works, such as the "Colliget" and the Commentary on Galen of Averroes, were largely spared; yet in the fourteenth and fifteenth centuries the very name of Averroes, "the mad dog that barked against the Christ," not only became ecclesiastically accursed, but also began to signify loose life as well as free thought; a resentment of which there was no trace in Albert or Aquinas.

Averroism, however, held its ground at Padua, which had become celebrated for medicine as Bologna for law; and although Averroism, like any other philosophy taught as a separate study, decayed, yet, effete as it was, it kept the ground open at a time when the tide was turning against free thought; when the commercial supremacy of Venice was declining, when the Spanish Inquisition was established in Rome, and when even the influence of the Florentine humanists was rather against natural knowledge than for it. No doubt the coarse and disingenuous scepticism of the physicians of North Italy and their pretentious manners alienated the humanists, not only from themselves, but also from natural philosophers such as Telesius and Galileo; and Averroists and humanists alike stood by at the burning of Bruno. Harvey entered Padua at a fortunate time; he found Galileo engaged in teaching, and also in methodical research; and Galileo was not only a great discoverer, but was the first to formulate fully and clearly that method which we know under the name of the inductive method. The discovery of Greek texts had destroyed the conventional Aristotle and the conventional Galen; Gregory, by the reform of the calendar, had put the axe to the root of astrology; Newton was soon to carry terrestrial physics into celestial spheres; and Boyle was soon to create chemistry; while anatomy was fully awake already. In England, moreover, with the accession of Elizabeth more spacious times were assured, and Charles protected Harvey. Clinical teaching had been established at Padua by Fracastorius and Montanus, to be pursued in Heidelberg, Leyden and Vienna. Physiology, however, awaited Harvey. Servetus had buried his conception of the lesser circulation under a pile of theology; Columbo and Fabricius had prepared the way, not so much by the value of their discoveries as by their practice of the experimental method in this science; for the anatomists, Galenists to a man, had done next to nothing for physiology.

The genius and courage required to make discoveries like that of the circulation of the blood cannot be measured directly; there is no method of determining the specific gravity of such adventures; I have tried, however, to shadow forth the weight of the social systems, opinions, prejudices and habits against which Harvey's gigantic effort was made. Almost in the year of the publication of the "De Motu Cordis" (A.D. 1628), the Parliament of Paris issued an edict that no teacher shall promulgate anything contrary to the accepted doctrines of the ancients. Under such conventions Harvey's discovery burst like an earthquake; under corrupt Galenism, venerable sophistries, current abstractions bequeathed by realism, and long-winded dialectics on critical days, coctions, derivatives or revulsives, and dogmas based on uncritical subservience to texts. His work stood out even more ascendant against a lurid background of folk superstitions—of vampyres, witch-burning, magic, cabbalism, astrology, alchemy, chiromancy and water-casting. In terrestrial and celestial physics, Galileo, persecuted as he was, had some strong current with him; Copernicus was before him, Kepler was beside him: but in physiology upon the path of Galen the waters had closed as upon the track of a great ship, and among Harvey's contemporaries and immediate forerunners there was none to claim a share with him in the discovery of the central fact of physiology, or in his application of the method which opened the way to Pecquet, Glisson, Steno, Wharton, Willis, Haller and Bernard.

---

## THE ANNUAL CONGRESS OF THE GERMAN ANTHROPOLOGICAL SOCIETY.

THE thirty-first Congress of the German Anthropological Society was held in the University town of Halle from September 24–27. In addition to its rich University collections, a special interest is attached to Halle as being the seat of the oldest German society for encouraging the study of natural science, viz. the Leopoldina-Carolina Academy, which is thus comparable to the Royal Society in this country. To students of prehistoric archæology, the Prussian province of Saxony is chiefly interesting from the fact of the existence of copper-mines at Eisleben, some little distance from Halle. The meetings were held under the presidency of Prof. Virchow, assisted by Prof. Ranke. At the opening session on Monday, September 24, the presidential address (dealing with the general progress of anthropological study and teaching) was followed by a series of addresses from representatives of the University and town of Halle, of which that of the local secretary, Dr. Förtsch, is particularly noteworthy as containing a sketch of local prehistoric archæology, a field of research in which Dr. Förtsch has been particularly active, and which he has popularised with evident success. Of the subsequent communications to the Congress, the majority of which dealt with archæology, there appear to us most worthy of mention the discussion opened by Prof. Virchow on the "Earliest appearance of the Slavs in Germany," and the account (illustrated with excellent lantern slides) given by Dr. Birkner (Munich) of the investigation of the graves of the German Emperors in Speyer. Prof. v. Fritzsch (Halle) and Dr. Lehmann-Nitzsche (La Plata) rendered interesting accounts of discoveries of prehistoric man in Thüringia and in the Argentine respectively, the latter record being still the subject of investigation as regards the exact antiquity (Tertiary period) claimed for the find.

It is a matter of some surprise that the department of Physical Anthropology should not have been the subject of more papers than were actually presented at Halle, which University claims the two Meckels and Welcker among its former professors of anatomy. The chief contributions to this subject were those of Dr. Schmidt-Monnard (Halle) on the relation between the growth and the weight of children of both sexes; of Dr. Eisler (Halle) on the *Musculus sternalis*; and of Prof. Klaatsch (Heidelberg) on the method of research adopted by anatomists, illustrated specifically by observations on the "short head" of the Biceps femoris muscle in the mammalian series.

The chief excursion of the Congress was made on Wednesday, September 26, to Eisleben, where the copper-mines already referred to were visited, and demonstrations of copper-smelting were given by representatives of the Mansfeld Co. Subsequently the local collection of prehistoric pottery, &c., was inspected.

The concluding session was held on September 27, when the presidency (for the ensuing year) was assumed by Prof. Waldeyer (Berlin). It is a matter of interest to note that the Congress was made the occasion of circulating "special inquiry" sheets regarding the structure and building of boats in all parts of Germany. General proposals regarding cartography and systematic records for provincial localities were brought forward by Dr. Voss (Berlin).

In addition to the anthropologists already mentioned in the foregoing notes, there were present Freiherr v. Andrian-Werburg (Vienna), Prof. Hein (Vienna), Prof. Montelius (Stockholm), Prof. Koganei (Tokio), and others to the number of about one hundred and twenty.

## ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THE Section of Anthropology had a very successful session under the presidency of Prof. Rhys; indeed, it was one of the very best meetings of Section H in the history of the Association. Nearly every department of the subject was represented and that too by new and original contributions. It is interesting to note the different lines which members of the Universities of Oxford and Cambridge are at present taking up. The field of Classical Archæology is offering rich prizes to Arthur Evans, Hogarth, and Myres; while the expeditions of Hose, Stanley Gardiner, Haddon, Skeat, and others are providing material for a more complete knowledge of primitive peoples.

### I.—PHYSICAL AND EXPERIMENTAL ANTHROPOLOGY.

#### (1) *Somatology.*

Dr. John Beddoe, in a short paper on the vagaries of the cephalic index, described two long-headed skulls which had the general characters of dolichocephaly, but the one that appeared the more typical had a latitudinal index (living) of 82·3, owing to retarded ossification of the posterior part of the temporo-parietal suture; but for this the author thought the index would not have exceeded 77. Prof. Macalister, as at the last meeting of the Association, deprecated the importance usually ascribed to the cephalic index.

Prof. A. Francis Dixon read a paper, entitled "On certain markings on the frontal part of the human cranium and their significance." An examination of the frontal region of the cranium shows that, in many cases, grooves or channels are present on the bone, corresponding to the branches of the supra-orbital nerves. Their presence indicates a want in proportion between the growth in length of the nerves and the amount of expansion of the underlying part of the cranium. The nerves might be looked upon as constricting cords which become depressed in the developing bone as the cranium expands. In races in whom the grooves are common, and strongly marked, we would expect the presence of a tendency towards increased development and capacity of the frontal part of the cranium; while, on the other hand, in races in whom the grooves do not occur, or are rare, and but feebly marked, we would expect to find much uniformity in the shape and size of the cranium, indicating that none of its various parts are tending towards an increased development. In this connection it is interesting to note that the frontal grooves are almost never found in Australian and Tasmanian skulls, that they are rare among Melanesians, slightly more common among Polynesians, while among Bushmen and negroes, especially in Zulus and Kaffirs, they are very common, and often extraordinarily well marked.

Mr. W. L. H. Duckworth described nine crania collected by Mr. J. Stanley Gardiner in his expedition to Rotuma. As might have been expected from the position of the island, the skulls could be resolved into two types, one of the form of cranium usually found among Polynesian peoples, though possessing something of a Mongolian aspect; the other was of distinctly Melanesian affinities. The paper was well illustrated with lantern slides.

A second paper by Mr. Duckworth was on some anthropological observations of the Pangan tribe of aborigines in the Malay Peninsula made by Mr. J. Laidlaw in the Skeat Expedition. Mr. Duckworth measured one adult male skeleton the stature of which was about five feet, which is the average height of the men measured by Mr. Laidlaw. The latter describes the people as having a skin colour of varying shades of dark brown, and the black hair is in some cases frizzly and in others more or less curly or wavy. Mr. Duckworth regarded the skull as of a negroid type with infantile characteristics. It is probable that the skeleton in question belonged to a half-breed Negritto and Malayan individual.

The developmental changes in the human skeleton from the point of view of anthropology were described by Dr. David Waterson. A comparison was instituted between the bones of the embryo and those of the lower races of mankind and of the higher apes, both as regards their relative length and their characters. As it has been shown that the curvature of the spine in the lumbar region is a post-natal development, and one adapted to the assumption of the erect attitude by the infant, it can also be shown that in a similar way the configuration of the bones of the lower extremity alters after birth, before the infant can stand erect.

Prof. A. Macalister discoursed on perforate humeri from ancient Egyptian skeletons. In examining those from Libyan graves, he was struck with the large number of humeri which had a supra-articular perforation, the proportion of such among these old Egyptian remains being much greater than among other races. He found that these perforations reached 57 per cent. among the ancient Egyptians, whereas among average English people they ranged about 3 per cent., and 10 per cent. among Neolithic skeletons, while the percentage rose to 53 in the skeletons of Indians from Arizona.

A paper on the sacral index was read for Prof. D. J. Cunningham. Inasmuch as the true length of the sacral portion of the vertebral column is not indicated by the shortest distance between the apex and base of the sacrum, but rather by the length of the curve formed by the sacral vertebræ, it is proposed that, in making measurements for the determination of a sacral index, "length" should be measured by using a tape along the concavity of the sacral curve, and not by calipers, one limb of which is placed upon the base and the other on the apex of the sacrum. Breadth (measured by calipers in the ordinary manner) multiplied by 100 and divided by length, measured in the manner indicated, gives the true sacral index. The curvature of the sacrum may be conveniently plotted by taking a tracing from a strip of soft metal which has been previously adapted by pressure to the front of the sacrum along its middle line. The index of curvature may be expressed by the number derived by multiplying the height of this plotted curve by 100 and dividing by the number corresponding to the true length of the sacrum.

Dr. Cunningham communicated a second paper on the microcephalic brain, which also was read by Dr. Dixon, and illustrated with a large number of lantern slides. The brain of the microcephalic idiot may exhibit features which do not merely represent a "fixed" embryonic condition. In one specimen the arrangement of the fissures and sulci is found to approach more closely the ape than the human type, and in almost every furrow some simian character can be detected. These simian characters must not be considered mere fœtal conditions rendered permanent. The ape-like condition existing in this brain does not as a whole correspond to that of any one ape, or group of apes, but there is a complicated mixture of features some of which are characteristic of high apes, while others find a parallel in the brain of low apes. The microcephalic brain may be regarded as a partial "atavism." So far as its surface markings are concerned, the specimen noted has reverted in part, or wholly, to an arrangement which, in all probability, existed in some early stem-form of man

Dr. J. G. Garson read a paper, with lantern illustrations, on a system of classification of finger-prints.

(2) *Psychology.*

Prof. G. J. Stokes read a paper on the sense of effort and the perception of force, and Prof. Marcus Hartog contributed another on interpolation in memory. In the discussion on the latter paper, Prof. Lloyd Morgan contended that psychologists had not so completely overlooked the practical perceptual judgment as Prof. Hartog seemed to suppose.

Mr. E. W. Brabrook presented the final report of a committee which has been acting in conjunction with the Childhood Society for the scientific study of the mental and physical conditions of children.

### II.—ETHNOLOGY.

(1) *Sociology.*

Mr. E. S. Hartland read a paper that attracted a good deal of attention, on the imperfection of our knowledge of the black races of the Transvaal and Orange River Colonies.

(2) *Technology.*

Dr. A. C. Haddon read a paper, illustrated by lantern slides and specimens, on the textile patterns of the Sea-Dayaks. The Sea-Dayak women weave short cotton rep petticoats and cotton sleeping wraps which are covered with beautiful and often intricate patterns. The patterns are made in the following manner: the warp is stretched on a frame, the woman takes the first fifteen to thirty strands and ties them tightly with strips of leaves at irregular intervals, according to the design, which she carries in her memory. The next fifteen to thirty strands are similarly tied, and this process is repeated until all the threads have been utilised. The warp is then removed from the frame and dipped in a reddish dye, which colours the free portions of the warp, but the tied-up portions remain undyed; thus a light pattern is left on a coloured background, when the lashing is untied. If a three-colour design is required, as is usually the case, the first lashing is retained, and various portions of the previously dyed warp are tied up; the whole is immersed in a black dye, and then both sets of lashing are untied. The pattern is thus entirely produced in the warp. By far the greater number of these designs are based upon animals, whereas most of the patterns carved by the men on wooden and bamboo objects are derived from plant motives. The decorative art of the Sea-Dayaks of Sarawak differs in character from that of the Kayans, Kenyahs, and other inland tribes.

A paper was read by Mr. W. Rosenhain on the making of a Malay "Kris." This, it was explained, was a species of native sword, and the paper dealt with some specimens of Malay metal work which had been submitted to the writer for microscopic and other examination by Mr. W. W. Skeat. By means of many lantern views Mr. Rosenhain exhibited samples of this kind of weapon, showing especially the "damask" pattern of the "Kris." Swords of this description were composed of many strands of two kinds of metal. The body of the blade was made of steel, a layer of laminated "damask" iron was welded upon each side of the central layer. A thin layer of steel was then welded on, outside the "damask" iron. The author was of opinion that the striated "damask" effect was due to the opening of the loose welds in the "damask" iron during the forging of the blade, steel being driven between the laminæ. The outside layer of steel was entirely ground away during the process, and when the compound surface so produced was "etched" by the pickling process employed, the more readily corroded steel was attacked, leaving the edges of the layers of iron as a series of narrow projecting ledges. The tools of the Malay goldsmith were then carefully described, and subsequently a description was given of the micro-structure and composition of Malay bronzes. The concluding part of the paper dealt with the Malay method of producing chains by casting, a practical illustration of the method being given by Mr. Rosenhain on the platform.

Prof. Macalister said that the older Universities of this country were frequently reproached for not doing anything practical. He felt, however, that Mr. Rosenhain had that afternoon removed a great deal of that reproach by practically demonstrating for them the process of casting metal chains practised by the Malays.

Prof. H. Louis read a "Note" on the "Kingfisher" type of a Malay "Kris," which was illustrated by specimens.

This was a type of "Kris" used only in a very limited area in the north-east of the Malay Peninsula; it was, however, rare even in its own home. The Malay legend of its origin, he remarked, was that a party of Malays from the Bugis Islands invaded that portion of the Peninsula many centuries ago. One of their leaders was known as "the Kingfisher"—presumably on account of his rapid movements. The invasion was successful, but the leader fell in one of the last engagements, and after his death his followers carved their Kris handles into shapes resembling the Kingfisher's head and beak. Under Chinese influence the pattern became more and more ornate, being modified by the Chinese "Dragon," until it reached the present fixed type.

Dr. Haddon gave an afternoon lantern demonstration on the houses and family life in Sarawak. He exhibited a series of about fifty lantern slides of photographs taken during his recent expedition to Sarawak, selected to illustrate the type of houses common among the settled inland tribes of Borneo and the everyday life of the people.

Mr. W. Law Bros delivered an afternoon lantern lecture on some Indian monuments, illustrated by numerous beautiful slides taken by himself.

A paper, with lantern illustrations, on permanent artificial skin marks was read by Mr. H. Ling Roth. Whatever might have been the original idea, ultimately its objective became manifold. Mr. Ling Roth described four systems or methods of tattooing. The Tahitian method of "tattaow" was performed by pricking or tapping with pigment, and produced the smooth result such as was seen in our soldiers and sailors. The Maoris of New Zealand adopted this pricking method, and also a cutting method performed with a sharp, adze-like edge like a narrow chisel. This produced slight but permanent grooves in the skin. The third method was that adopted in West Africa, and was similar to the second, but the grooves produced were deeper and wider, and generally no pigment was used. Lastly, there were the curious raised marks of the Tasmanians, Australians and Melanesians generally, and the Central African tribes. In this case the cuts were made with sharp edged stones, and were continually reopened or irritated by the insertion of vegetable juices or sand. Hence was produced an abnormal amount of reparative action, and the wounds did not heal naturally as healthy concave scars, but developed into nodulous growths of sometimes considerable size. For these four methods Mr. Ling Roth suggested a nomenclature—namely, tatu, moko, cicatrix and keloid.

Mr. Davis read a paper on the system of writing in ancient Egypt for Mr. F. Ll. Griffith, and whilst doing so illustrated his remarks with very clever sketches on the blackboard. Egyptology has now reached a position among the sciences from which it may contribute trustworthy information for the benefit of kindred researches. Egyptian writing consists of Ideographic and Phonetic Elements, the signs serving as:—(1) Word-signs; (2) Phonograms; (3) Determinatives. The highest development shown is an alphabet, which, however, is never used independently of other signs: it is apparently not acrophonic in origin; it represents consonants and semiconsonants only, vocalisation not being recorded by Egyptian writing. No advance can be detected in the system from the beginning of the historic period to the end, notwithstanding some improvements in practical working which facilitated the use of cursive writing. Phonograms derived from word-signs. The end of the native system was brought about by the gradual adoption of the Greek character—beginning, perhaps, in the second century A.D. If any radical improvement was ever made in the Egyptian form of writing, that improvement must have taken place at or after adoption by another people: *e.g.* some have supposed that our alphabet was derived by the Phœnicians from Egypt; but any such derivations are at present entirely hypothetical.

A paper was read by Mr. Arthur J. Evans on the new scripts he has recently discovered in Crete; an account of his researches has already appeared in NATURE (p. 526).

(3) *Religion.*

Some peculiar features of the animal-cults of the natives of Sarawak, and their bearing on the problems of totemism, were discussed in a paper by Dr. C. Hose and W. McDougall.

Customs had previously been observed that seemed to indicate the existence of a well-developed totemism, either at the present time or in recent times, among the natives of Sarawak. Information bearing on this subject was therefore collected as diligently as possible from various tribes.

A great number and variety of peculiar rites and customs were found to be observed by the people of the different tribes in their dealings with animals and plants. This paper was confined to giving (1) a general account of the customs of one of the inland tribes, the Kenyahs; (2) to describing the "Nyarong," or spirit-helper of the Sea-Dayaks, and some similar institutions among the other tribes; and (3) to pointing out the bearing of our observations on the totem problem.

The Kenyahs are a warlike, agricultural people living as isolated communities of twenty to fifty or more families, each community inhabiting a single long house built on the river-bank. Their religion is peculiar, in that they believe in a beneficent Supreme Being and a group of departmental deities, while they attribute to every agent that affects their lives a spirit that must be properly respected and, if necessary, propitiated. Most important to them of all the animals is the common white-headed hawk. He brings messages of warning and advice from the Supreme Being to those who know how to read the signs he gives, and he is consulted before every undertaking of importance, and sacrifices of fowls and pigs are made to him. A wooden image of the hawk stands before every house. Several other birds give them omens of lesser importance, and none of these may be killed or eaten. The domestic fowl is killed as a sacrifice to the hawk or other powers, and its blood is sprinkled on the altar-posts of the gods and on the persons taking part in various ceremonies, especially peace-making ceremonies. The domestic pig is sacrificed in much the same way. The spirit of a pig is always charged with some prayer to be carried to the Supreme Being, and the answer is read from the markings of its liver. The crocodiles are regarded as a friendly and allied tribe, and may be killed in retaliation only. No Kenyah will kill a dog, and the dead body of a dog is regarded with fear. Kenyahs will not eat the flesh of deer or horned cattle, and there are many restrictions on touching or using any parts of them. Only old or renowned warriors will wear or touch the skin of a tiger. One house is decorated with carvings of the gibbon on every large beam, and all Kenyahs have a dread of the Maias and the long-nosed monkey. There thus seems to be every degree of regard paid to the different beasts, from the mere uneasy feeling in the presence of the uncanny, long-nosed monkey to the elaborate cult of the hawk, and the nature of the respect paid to any species seems in nearly every case to be the direct expression of the impression made on the barbarian's mind by the behaviour of the beasts.

*The Spirit-Helper.*—Every Sea-Dayak hopes to be guided and helped all through his life by a spirit which announces itself to him in dreams and takes up its abode in some peculiar natural object or in some animal. In the latter case the Dayak will never kill or eat one of the same species of animal, and will lay the same prohibition on all his descendants, so that a whole family may come to pay especial regard to one species of animal for many generations. A similar institution occurs, though less commonly, among the other tribes. In such cases we seem to be able to trace sometimes the actual origin and growth of a totem; but neither among the Sea-Dayaks, nor the inland tribes of Sarawak, could the people be said to be in a totemistic stage of culture, nor was there sufficient evidence of an earlier totemistic cult. Mr. Hartland complimented the author on his caution and carefulness. He agreed with Dr. McDougall in regarding these animal cults as affording little proof of totemism as a stage in social or religious custom.

Dr. E. B. Tylor read a paper, by Mr. W. G. Aston, on the Japanese *gohei* and the Ainu *inao*." The leading idea of the paper was the illustration of the principle in religious development by which an object which was in the first instance simply an offering to a god has in the lapse of time been conceived as the embodiment of the god, or even as a distinct and independent deity. In ancient Japan the offerings to the gods were hemp and bark fibre, with cloth made from these materials. In later times there was substituted a small quantity of paper made of the same bark material and attached to a wand in the form known to us as the *gohei*. With the change of form the original character of the *gohei* as offerings was forgotten. They were looked upon as receptacles of the god, or embodiments of him, and honour was paid to them accordingly. At festivals it was supposed that the god descended into the *gohei* on a certain formula being pronounced by the priest. Hypnotic practitioners also used these objects, through which the deity who inspired them was supposed to enter their bodies. In other cases the devotees went further, and constituted the object which was originally an offering into a distinct and independent deity. The Ainus of Yezo use in their worship whittled sticks called *indo*, which have a general resemblance to an old form of the *gohei*, and are doubtless a cheaper substitute. The *inao*, like the *gohei*, are primarily offerings, but in some cases they ultimately gain direct worship as gods, having become, in short, genuine fetishes. Another link between the *inao* and the *gohei* is found in certain whittled sticks which a century ago were in use in Northern Japan for striking women with, as at the Roman *Lupercalia*, in order to secure fertility. Similar sticks, after consecration by the Shinto priests, were formerly used at Kiota to kindle the household fire at the new year to avert possible pestilence.

Mr. David Boyle, curator of the Toronto Museum, read a paper on the paganism of the civilised Iroquois of Ontario. Notwithstanding the contact of the Iroquois, or Six Nation Indians, with white people for more than three hundred years, a very considerable number of the former have retained many of their old-time beliefs with the appropriate ceremonies. Of four thousand Caniengas (Mohawks), Senecas, Cayugas, Onondagas, Oneidas and Tuscaroras now residing in the Grand River Reserve, within sixty miles of Toronto, Ontario, fully one-fourth continue to observe the ancient feasts or dances connected with the growth and ingathering of corn and fruits, and for desired changes in the weather, as well as for the curing of disease. Some modification in the ceremonies was made about a century ago by an Onondaga named Ska-ne-o-dy-o, who announced himself as a prophet who had paid a visit to the abode of the Great Spirit. The changes introduced by him, however, have not by any means removed the pagan character of the native beliefs, although he certainly did attempt to imitate some Christian observances. Still the addresses of the medicine-men retain most of the old-time forms, although their significance in many cases is lost and even the meaning of numerous words is no longer known. The leading idea of the present form of worship is that of a great spirit; but this has been acquired from missionary sources, and although the Indians have adopted the idea of a heaven, they do not believe in any hell. The quoted examples of petitions addressed to Rawen Niyoh, the Creator, illustrated the lack of assimilation of the old and new forms. One of the most characteristic ceremonies connected with the Iroquois paganism is that of the sacrifice or burning of the White Dog at the new year feast during the February moon, when the spirit of the dog, accompanied by offerings of tobacco, conveys to *Niyoh* information respecting the condition of his "own people" on the Grand River Reserve.

## III.—ETHNOGRAPHY.

The Anthropology of West Yorkshire was the subject of a communication by the venerable Dr. John Beddoe. He remarked that the most striking qualities of typical Englishmen had been thought to be strongly developed in Yorkshire. Among these, he feared, was the defect of imagination so often found in those who called themselves, with some pride, practical men. Such men entertained a positive dislike, and even contempt, for knowledge of which they did not see the immediate use. This character was not British, Celtic, or Welsh.

Dr. Beddoe's impression, acquired by simple inspection, is that in the central parts of the West Riding, and notably at Leeds, a prevailing type is characterised by an oblong, or rather trapezoidal, head, inclining to be broad rather than narrow, with a vertical forehead, smooth and not prominent brows, and a straight profile, with a straight or sometimes concave nose. The smooth brows dissociated this type from that of the Bronze race and the squareness from the smoothly elliptic or oval one of the Southern Saxon. He was inclined to call it Anglian. Light hair was prevalent hereabouts, and also in the mountainous regions to the north and south.

On the whole, he thought the eastern and central regions of Yorkshire, judging by physique, less purely Teutonic than Teesdale or the Wapentake of Morley, though more so than Craven.

The author discussed the question whether any considerable British or pre-Anglian element remained in the country around Bradford. Without coming to any positive conclusion, he was disposed to consider the inhabitants of these parts as mainly Anglian in type. More British blood remained further north, in Craven. A prevalent type about Leeds seemed to him to resemble the Burgundian Belair type of His and Rütimeyer.

Mr. J. Gray read a paper on physical characteristics of the population of West Aberdeenshire from observations made and statistics compiled by himself and Mr. J. F. Tocher. These observations, he said, were made at a Louach gathering in Strathdon, an isolated district lying right at the head of the Don Valley, with the principal object of ascertaining if any difference existed between the people in the upper ends of the river valleys and those on the eastern seaboard. It was reasonable to conclude, from the anthropological statistics compiled, that in Aberdeenshire at some distant date an early, tall, broad-headed, dark-haired and blue-eyed people, descendants of men of the Bronze age, who had perhaps come from South-east Europe, had been driven inland to the upper ends of the valleys and hills by later immigrants from North Germany who were shorter, had narrower heads, and were of a blonde type.

Mr. J. L. Myres then read a communication from Mr. D. Randall-MacIver on the present state of our knowledge of the modern population of Egypt, in which it was pointed out that whereas we had from statues and paintings, and especially from the skeletons found in recent excavations, a very fair idea of the composition and changes in the ancient population of Egypt, the interpretation of that evidence and of the problems in Egyptian history which it might be expected to solve was seriously hampered by the absence of corresponding evidence in regard to the modern population.

The Committee for the Ethnological Survey of Canada continue its most useful and necessary work, the report presented at this meeting being of exceptional value. The work of the past year has furnished conspicuous evidence of the great importance of securing ethnological data with as little delay as possible. While this is eminently true with respect to the white population, which is experiencing new and marked changes almost every year, in consequence of the introduction of foreign elements, often in large numbers, it is more particularly true with respect to the native Indian population. In many localities the original blood has become so diluted by intermarriage with whites that it is often a matter of great difficulty to find an Indian of pure blood. Proximity to settlements of white people has resulted in a more or less profound impress upon the social life and tribal customs, which are fast becoming obsolete and forgotten. The old chiefs who have served as the repertories of traditional knowledge are rapidly passing away, and with their death there disappears the last possibility of securing reliable data of the greatest value. Conspicuous instances of this kind have been brought to notice during the past year, especially in the case of the British Columbia Indians, whose ethnology is of the greatest interest and importance in consequence of their possible connection with the people of Eastern Asia. At present the great difficulty of securing competent and willing investigators is one of the most serious obstacles to be contended with, and it is believed that the often considerable expense involved in the prosecution of such work is largely accountable for this condition of affairs.

It is gratifying to note that the Department of Education for Ontario has taken a very practical and active interest in ethnological studies in that province, and that it provides for the publication of the results of research in its annual reports. Evidence has latterly been accumulating to indicate the presence at one time of numerous aboriginal settlements in localities which were very sparsely inhabited when first visited by the white explorers.

The committee appointed to carry out investigations on the natural history and ethnography of the Malay Peninsula presented their report, which had been drawn up by Mr. W. W. Skeat, the leader of the expedition.

The expedition itself was composed of members of the Universities of Oxford and Cambridge. The objects of the expedition were to carry out a scientific survey, in which ethnology, zoology, botany and geology should be included, of the little known Malay provinces of Lower Siam. The report stated that some very curious racial problems were found in the district arising out of the fusion of two antagonistic race elements. The most interesting problems were found in connection with the very primitive jungle tribes of the interior, concerning which much valuable information was obtained. The inhabitants were found to be for the most part Malay, who had become subject to Siamese influence. One little known tribe—the sacred tribe of the Prams—claimed to have come from India, and to have established themselves in the country previous to the coming of the Malays. The expedition was successful in obtaining a copy of their sacred book, from which it is believed an account of the origin of the tribe may be obtained. One small jungle tribe of Pangans was heard of, but though a forced march was made to reach them, the wild men had heard of the approach of the expedition, and had taken flight. Their late dwelling-place, a cave under a projecting rock, was photographed, as also were the very curious "tree-graves" used by the Siamese. This "tree-grave" burial, however, was now condemned by the Bankok authorities, and would become extinct before long The most interesting of Malay industries observed was the manufacture of damasked "krisses." Near the head-waters of the Muda a tribe of from twenty to thirty individuals was found living in a long barrack-like shelter of palm leaves. From them and from a neighbouring tribe valuable information as to their manners, customs and language, as well as full measurements of a few individuals, and some probably unique phonographic records of their songs, had been obtained, which were of an extremely simple and primitive character. It was found also that many of the leading Malay industries were being rapidly modified by the introduction of European methods and appliances, and it was now the rarest and most difficult thing to obtain cloth actually made of home-spun thread, the use of Singapore silk and aniline dyes being already the fashion everywhere.

### IV.—ARCHÆOLOGY.

Mr. A. M. Bell then contributed a paper on the occurrence of flint implements of palæolithic type on an old land-surface in Oxfordshire, near Wolvercote and Pear-tree Hill, together with a few implements of various plateau types. He stated that a large section of the quaternary river-gravel there produced the usual fauna and many fine implements of human workmanship. This gravel cut into and was therefore newer than a previous land surface, a portion of which was found at Wolvercote and another within half a mile at Pear-tree Hill. In both places flint instruments of palæolithic type, together with bulbed flakes and a few implements of plateau-type had been found. In every case these flints were vitreous, a point which distinguished them from those belonging to the river-gravels at Wolvercote. The older surface has been previously described as Northern Drift. Mr. Bell said he supposed it to be a *remaniement*—*i.e.* a re-handling or working over of the true Northern Drift, but deposited under semi-frozen conditions. It must be anterior to the river-valley, and consequently its relics of man were the oldest as yet obtained from the Thames valley. The drift in question most resembles the drifts of Caddington described by Mr. G. Worthington Smith and some sections on the Lower Greensand near Limpsfield, both of which are implementiferous, and the author would correlate the Wolvercote and Pear-tree Hill surface with these drifts.

A paper by Mr. J. Paxton Moir on stone implements of the natives of Tasmania, was read by Prof. E. B. Tylor. Examples of tools prepared with the help of grinding, and furnished with handles, were very rare, and were evidently of Australian origin. The Tasmanian implements were variously used—as, for example, by the women to cut notches in the bark of trees as an assistance in climbing; in the making of the Tasmanian spear, by scraping it straight and smooth; in grooving the handle of the Tasmanian club; and in sawing bones.

Prof. Tylor then proceeded further to add his own views on the Stone age in Tasmania as related to the history of civilisation. Inasmuch as the stage of civilisation attained by any people was of necessity closely associated with the nature of the implements in their possession, we might fairly assume that the development and habits of Europeans of the earliest authentic Stone age were essentially similar to those of the Tasmanians. What then, could we infer as to the earliest human races—the earliest, that is, after we had crossed the great gulf of the unknown which, on the evolutionary hypothesis, existed between the animal and the man? We found, taking the Tasmanians as representative of the earliest grade of society, that these people had no bows and arrows or throwing stones, but they had spears and clubs. They had houses and boats, but of the rudest imaginable type. They knew of fire, and could make it by the fire stick. With their stone implements they prepared and utilised the skins of animals. They made basket-work—in fact, the basket-weaving art had not substantially advanced from the earliest ages of which we had any knowledge until the present. They had a mythology, with a Greek-like legend, as to the origin of fire; and lastly, they had religious ideas, lower and ruder than those of the North American Indians, but on substantially the same lines. This circumstance—that the Tasmanian natives represent the most ancient known beginnings of human civilisation, while at the same time they were so recently a real, living and known people—rendered all knowledge which could be acquired concerning them a contribution of priceless value to the history of mankind.

Mr. H. Ling Roth said that some eighteen months ago he had received from a Yorkshire gentleman, Mr. J. Backhouse Walker, an account given by an old Australian settler, who in his youth had come across a group of black fellows whilst they were actually engaged in making these stones. The first process was simply to split them by hurling them violently on the rocky ground, and some stones were at once used in this rough shape for cutting up kangaroo meat, whilst other stones were prepared by chipping. At one period, doubtless the Tasmanians covered the whole of Australia; and they were subsequently almost swept away—only scattered representatives being left in small areas—by another race.

Dr. A. C. Haddon made a communication on relics of the Stone age of Borneo (illustrated by lantern slides and specimens). Dr. C. Hose, the Resident of the Baram District of Sarawak, obtained numerous examples of stone implements from various interior tribes in his district; these he has generously presented to the University of Cambridge. The implements are made of various rocks, including fibrolite, impure sandstone, arkose, silicified limestone, shale, andesite and chalcedony. The form, too, varies greatly; some are obviously axe heads, others adze blades, while certain cylindrical forms, with a more or less cup-shaped cutting end, were probably used to extract the pith from the sago palm. In the collection are several stones of irregular form; the former use of some of them is problematical, but they have recently been used as touchstones. The natives have a high regard for these stone implements, which have in their eyes a sacred character, and it is very difficult to persuade their owners to part with them. In all cases fowls had to be sacrificed to appease the spirits. The implements are stored with other sacred objects, and most of them are believed to be teeth, or toe-nails, of Baling Go, the Thunder God.

Mr. Butler Wood read a paper, with a map illustration, on the Prehistoric Antiquities of Rumbald's Moor, between Bradford and Ilkley. The stone implements found there, he said, consisted of axe-heads, arrow-heads, awls, spear-heads, knives and scrapers. Several fine specimens were exhibited. Baskets full of flint chippings scattered about in a very limited area seemed to prove that it was a place of fabrication of flint instruments, for flint *in situ* was not found within fifty miles. About half a dozen bronze axe-heads had been found at lower elevations. So far as evidences of interment went, the barrows were unsatisfactory. There was a double stone circle within four miles of Bradford Town-hall containing in the centre a boulder with a cup and ring mark on it. He hoped the Corporation of Bradford would not permit it to continue neglected, but would preserve it as a valuable specimen of antiquity. Mr. Wood also briefly mentioned the earthworks and the so-called pit dwellings which seemed to have been attempted excavations for iron. Springs of water were always found near these excavations.

Dr. Haddon emphasised Mr. Wood's observation as to the necessity for the preservation of local antiquities. It was the duty of the section to bring to the notice of local authorities the fact of the existence of valuable archæological remains in the district, and he hoped the Press would help him to insist upon the fact that it was the duty of all the local authorities to preserve their antiquities as well and as long as possible. It had been observed by Mr. Wood that if steps were not taken the double stone circle would soon be worn away and disappear owing to pedestrians walking recklessly over and about it; and he hoped that as a result of this paper and of the feeling expressed by the section, the proper authorities would take such steps as would effectually preserve this ancient stone structure. He also thought it a pity that the three Saxon crosses at Ilkley were not placed inside the parish church, and the cup and ring markings on boulders preserved at Ilkley would be better protected if a light shed was erected over them.

An excellent paper by Mrs. Armitage on some Yorkshire earthworks describes a particular kind of earthwork, very common in Yorkshire and in other parts of England, consisting of a moated hillock with a banked and moated court attached. This type of fort has been attributed in turn to the Britons, Romans, Saxons and Danes, with equal improbability. The theory most general at present is that it is Saxon. But Saxon strongholds were built to shelter all the people of the neighbourhood, and were therefore of large area, while these earthworks are evidently intended to protect some individual chieftain and his personal following, as is shown by their small area. There is positive evidence that the Normans built earthworks of this kind in the eleventh century as the bases of wooden castles, and these moated hillocks are still very numerous in Normandy. They are called *mottes* in Norman-French, and this word is found in various parts of England in the form *mote*. An inquiry into the castles known to have been built by the Normans when they first came to England shows that almost all these castles had mottes, while the *burhs* or *boroughs* built by the Saxons never have these appendages, unless a Norman castle-builder has been at work there. The recognition of the Norman origin of these castles would help to solve an historical puzzle—how the Normans were able to hold England down. It was by a system of small fortified posts scattered all over the country that the action of the central machinery was carried into the remotest parts of the kingdom.

Mr. D. G. Hogarth read a paper on the cave of Psychró in Crete, which was copiously illustrated by excellent lantern slides. It has been known for some years that a large cave above the village of Psychró, in the Lasithi district of Crete, was a repository of primitive votive objects in bronze, terra-cotta, &c. As this cave is situated in the eastern flank of the mountain which dominates the site of ancient Lyttos, and is the only important cave known in the neighbourhood, it was conjectured that it was the Lyttian grotto connected with the story of the infancy of Zeus in the legend, whose earliest version is preserved by Hesiod. A thorough exploration of it has served fully to confirm this view. The cave is double. A rude altar was discovered in the middle of the upper grotto, surrounded by many strata of ashes, pottery and other refuse, among which many votive objects in bronze, terra-cotta, iron and bone were found, together with fragments of some thirty libation tables in stone, and an immense number of earthenware cups used for depositing offerings. The lowest part of the Upper Grotto was found to be enclosed by a wall partly of rude Cyclopean character, and partly rock-cut; and within this Temenos the untouched strata of deposit ranged from the early Mycenæan age up to the Geometric period of the ninth century B.C. or thereabout. Only very slight traces were found of later offerings. The earliest votive stratum belongs to the latest period of the pre-Mycenæan age, that marked by the transition between the "Kamáraes" fabric of pottery and the earliest Mycenæan lustre-painted ware. But below all is a thick bed of yellow clay, containing scraps of primitive hand-burnished black and brown pottery, mixed with bones of animals. This bed seems to be water-laid, and to be prior to the use of the cave as a sanctuary.

The southern or Lower Grotto falls steeply for some 200 feet to a subterranean pool, out of which rises a forest of stalactite pillars. Traces of a rock-cut stairway remain. In the chinks in the lowest stalactite pillars, a great many of which were found still to contain toy double axes, knife-blades, needles, and other objects in bronze, placed there by dedicators, as in niches. The knife-blades and *simulacra* of weapons are probably the offerings of men; the needles and depilatory tweezers of women. The frequent occurrence of the double axe, not only in bronze, but moulded or painted on pottery, found in the cave, leaves no doubt that its patron god was the "Carian" Zeus of *Labranda*, or the *Labyrinth*, with whom perhaps his mother, the Nature goddess, was associated, and the statuettes probably represent the two deities. Here was the primitive scene of their legend, afterwards transferred in classical times to a cave on Mount Ida.

Mr. Arthur J. Evans remarked that the cave was one of the most ancient shrines of the classical world bound up with the earliest cult of Zeus. Mr. J. L. Myres suggested that the eras of Cretan civilisation covered by the objects found in the cave might go back, at furthest, to the twelfth Egyptian dynasty, and extend down to the eighteenth dynasty.

A report of the committee appointed to co-operate with the Silchester Excavation Fund Committee was read by Mr. E. W. Brabrook.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. J. Larmor, F.R.S., has been appointed a member of the General Board of studies. Mr. F. C. Kempson and Dr. G. F. Rogers have been appointed demonstrators of anatomy; Mr. C. T. R. Wilson and Mr. J. S. E. Townsend have been appointed demonstrators of physics.

The Gedge Prize for physiology has been awarded to Mr. J. Barcroft, King's, and Mr. H. H. Dale, Trinity.

The Biennial election to the Council of the Senate will take place on November 7. Dr. Hill, Mr. Austen Leigh, Sir Richard Jebb, Dr. Kirkpatrick, Dr. Langley, F.R.S., Mr. Mollison, Mr. Shipley, and Dr. Keynes are the retiring members. In the absence of any acute issue it is not unlikely that most of these may be re-elected.

A syndicate is about to be appointed to consider what steps, if any, should be taken towards the better organisation of instruction in military subjects within the University. The question has been brought up by a memorial signed by a large number of influential residents in Cambridge, who desire the establishment of a closer connection between the University and the Army.

The High Court has issued an order varying the conditions of the Gedge Bequest for the encouragement of physiological research, whereby advanced students are admitted to the competition, provided they are of not less than three or more than five years' standing.

The examiners in sanitary science announce that sixteen candidates have, at the recent examination, become qualified for the University Diploma in Public Health.

On October 22, the number of freshmen who matriculated was 841, including fifteen advanced students. Last year the number was 883.

Prof. Darwin, F.R.S., has been elected a member of the Financial Board, Dr. Larmor a member of the Observatory Syndicate, Mr. Berry an examiner for the Mathematical Tripos Part I., and Prof. Lamb, Mr. Richmond, Mr. Baker and Mr. Macdonald examiners for Part II.

A VALUABLE address on "Famine in India" was given by Prof. Robert Wallace at Edinburgh University on October 18, to inaugurate the course of lectures on Colonial and Indian agriculture, specially endowed by Mr. Robert and Mr. John Garton, of Newton-le-Willows, Lancashire, and permanently attached to the chair of agriculture and rural economy in the University. The course is to be a part of the regular work to be done during the winter session of five months, and is to be delivered free to present and past students of the department of agriculture. As Prof. Wallace will be largely concerned with agricultural conditions in India and the Colonies, and their possible development, the subject of his inaugural lecture at what may be the closing epoch of the most prolonged, if not the most disastrous, of famines to which the Indian peoples have been periodically subjected was an appropriate one. "One of the greatest problems of the future," he remarks, "will be the supply of food for the rapidly-increasing, teeming millions of population. The haphazard method of production by which the accumulated resources of temporary fertility have been drawn upon as successive new unpopulated areas of virgin soil have been placed under requisition must sooner or later cease, and more scientific methods of cultivation and better systems of management must extract more bountiful results from new and improved breeds of plants and of domesticated animals. The expected era implies a more accurate knowledge of agricultural details, and a wider and more Imperial conception of the greater kindred questions than the present time affords."

THE museum which was opened by the Countess of Warwick at Stratford on October 18 will, we trust, lead to the establishment of many similar local museums. Prof. R. Meldola is largely responsible for the erection of the museum, for he advocated the formation of a collection of objects, and a permanent home for it, in his inaugural address to the Essex Field Club twenty years ago. The suggestion was taken up by the more energetic members of the Club, and specimens of scientific interest gradually accumulated, but it was felt that a museum building was essential to make the collections of wide value. By the munificence of Mr. Passmore Edwards, and the enlightened policy of the Town Council of West Ham, a building, which has cost about £4000, has been erected adjoining, and communicating with, the Municipal Technical Institute. This is the building which was opened by the Countess of Warwick last week. The Corporation has agreed to warm, light and provide for the care-taking of the building, and to make a grant of not less than £100 per annum towards the curatorial expenses. The county collections, cases and cabinets of the Essex Field Club (excepting the Epping Forest collections, which are to be retained in the Forest Museum at Chingford) are placed in the museum. The Club undertakes the selection and scientific control of the collections, and will devote a sum of £50 per annum towards the curatorial expenses. From a pamphlet by Mr. William Cole, the honorary secretary and curator to the Club, we learn that the plan and scope of the museum has been clearly defined, and will be rigidly adhered to in order to avoid the error of gathering together a miscellaneous collection of incongruous specimens. The museum will be a local (Essex) one, supplemented by short series having an educational value, and designed to show the place of the local forms in the general scheme of classification of animal and vegetable organisms. The promoters aim at its eventually fulfilling three main purposes: (1) The instructive recreation of the ordinary visitor by means of carefully arranged sets of the chief forms of life inhabiting the district, and examples showing the nature and meaning of fossils and geological formations. (2) Collecting and preserving authentic series of all forms of life, recent and extinct, occurring in Essex, as well as geological and anthropological specimens. This is a matter of really great scientific importance in view of the changes in our fauna and flora now so rapidly being brought about by the increase of population and the consequent effacement of natural conditions in many parts of the county. (3) Assisting students and field-naturalists in identifying and studying the groups in which they are interested. It would facilitate the advancement of education and natural knowledge if a museum of this kind were connected with every Municipal Technical Institute.

The parliamentary vote for the University of London for the year 1900-1901 was £18,840 gross, but it only amounted to a net payment of £10, the difference being received from fees paid by candidates presenting themselves for examination by the University. Viewed as a strictly business concern, therefore, the University is practically self-supporting. Many people both at home and abroad will be astonished at the trivial amount actually paid by the Government in aid of its greatest University.

## SCIENTIFIC SERIALS.

*American Journal of Science*, October.—Notes on the Colorado Canyon District, by W. M. Davis. The Kaibab section of the canyon discloses the nearly even floor on which the horizontal Palæozoic strata rest. The floor is of complex structure. The fundamental schists with granitic dikes are overlaid in the eastern section by the heavy Unkar and Chuar series dipping eastward. The wedge in which the tilted formations terminate westward is a most remarkable geological structure, alike for its distinctness and for its significance.—Determination of minerals in thin rock sections by their maximum birefringence, by L. V. Pirsson and H. H. Robinson. The method described is an adaptation of Michel-Levy's colour diagram. The thickness of the rock section having been determined, the highest colour given in any of the numerous sections of the unknown mineral is observed, and by means of the diagonals the numerical value is noted which corresponds to the given colour in a section of the determined thickness. The maximum birefringence having thus been determined, the table of birefringences is referred to and the mineral usually found to be one of a group of several, among which it is easily distinguished by cleavage, colour and other optical properties. The authors add a table of birefractive powers, ranging from 0·287 (rutile) to 0·001 (chlorite).—Experiments on high electrical resistance, by O. N. Rood. An electric current travelling along a bad conductor has many analogies to a stream of pitch. It attains the end of the channel after a considerable interval, and if the resistance is very high, the potential at the end remains at zero. The author describes a number of experiments carried out with glass, silk, mica, jade, guttapercha, ebonite, amber and rosin. When glass, silk and mica were connected with one coating of a charged Leyden jar, it was found that within fifteen minutes the part farthest from the jar had assumed its potential. This was not the case with the other substances.

Ebonite showed a slight change of the opposite sign at the furthest end, probably due to prolonged inductive action.—New occurrences of corundum in North Carolina, by J. H. Pratt. The new occurrences are in an amphibole schist and a quartz schist respectively.—Products of the explosion of acetylene, and of mixtures of acetylene and nitrogen, by W. G. Mixter. Acetylene and ammonia yield hydrocyanic acid at a much lower temperature than is required to cause nitrogen to combine. It may be that ammonia is the first compound of nitrogen formed in the bomb, but the fact that a little ammonia is found among the products is not conclusive, as that may have resulted from the decomposition of hydrocyanic acid.

*Annalen der Physik*, No. 9.—Electric conductivity of pressed powders, by F. Streintz. Fine powders of platinum black, lampblack and graphite were prepared and subjected to great pressure. The resistance of 1 cubic mm. of platinum black was found to be 0·92 ohms at zero, as against 0·14 for ordinary platinum. The increase of resistance on heating was only half that of platinum. Lampblack showed a corresponding resistance of 40,000 ohms, and a very high negative temperature coefficient, therein resembling the electrolytes; while graphite, with its positive temperature coefficient, ranges itself among the metals.—Resistivity of bismuth in a variable magnetic field, by H. Eichhorn. Bismuth does not instantaneously lose the high resistance it acquires in a strong magnetic field. This is proved by mounting a bismuth coil on a rotating disc so that it traverses a magnetic field once during each revolution, and measuring, by means of contact pieces, the instantaneous resistance at various points of the orbit when at rest and in motion respectively.—Ratio of the thermal and electric conductivities, by E. Grüneisen. A very small proportion of arsenic added to copper suffices to reduce the thermal conductivity to one-tenth, and the electric conductivity to one-twelfth of its original value. In iron, the electric conductivity is much more sensitive to impurities than the thermal conductivity.—Reflection of kathode rays, by H. Starke. Kathode rays were made to impinge upon a metallic plate enclosed in a cylinder of the same metal, through a small opening in the end of which the rays entered. Another inner cylinder was used to measure the rays reflected by the plate and diffused by the gas, on the principle of Faraday's ice-pail. By putting the plate into two different positions, the diffusion and reflection could be separately estimated. The reflective power of aluminium was found to be 28·2, and that of copper 45·5.—Mechanical effect of kathode rays, by H. Starke. The author employs a kathode shaped like a propeller, but fixed. The rays impinge at an angle of 45° upon a thin plate of aluminium suspended above the kathode by means of a thin platinum wire. The results are negative so far.—Hardness of metals, by F. Auerbach. The author determines the hardness of metals by his method of finding the greatest pressure between a plate and a lens which the substance will stand without permanent deformation. Mild steel was found to have a hardness of 361, or that of quartz, hard copper 143 (like apatite), brass 107 (like fluorspar), gold 97, silver 91, aluminium 52, and lead 10.—Thermal conductivity of gases, by P. A. Eckerlein. The conductivities of air, hydrogen and carbonic acid are as 1 : 6 8 : 0·73, and the temperature coefficients are 0·00362, 0·00422 and 0·00352 respectively.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Entomological Society**, October 3.—Mr. G. H. Verrall, president, in the chair.—Mr. G. C. Champion exhibited specimens of *Trogophloeus anglicanus*, Sharp, from Plymouth; *Pachyta sexmaculata*, L., from Nethy Bridge, and *Anchomenus quadripunctatus*, De Geer, from Woking. Mr. M. Jacoby exhibited an ichneumon from Blandford parasitic on *Sirex*—*Rhyssa persuasoria*, and Col. Yerbury said that he had met with the same species in some numbers in Scotland. One female observed in the act of oviposition had thrust her ovipositor, which is about the consistency of a human hair, through an inch of fir trunk. Col. Yerbury exhibited:—(1) a rare sawfly, *Xyphidria camelus*, taken in Scotland this year at Nethy Bridge. The species is mentioned in the old books as extinct in the United Kingdom, and there are no modern specimens in the South Kensington Museum collection. (2) Rare diptera from Scotland including (a) *Laphria flava*, from Nethy Bridge; (b) *Chamaesyrphus scaevoides*, new to the fauna of Great Britain, from the Mound Sutherland, where it was common on Umbelliferæ under fir trees, one female also being taken on the path up Cairngorm near Glenmore Lodge; (c) *Microdon devius*; and (d) *Chilosia chrysocoma* at mountain-ash blossom, Nethy Bridge; (e) *Stomphastica flava*, two males from Golspie, September, 1900.—Mr. H. K. Donisthorpe exhibited (1) a specimen of *Drusilla canaliculata*, with the dead body of a *Myrmica* in its mouth, captured at Chiddingfold on July 17; (2) Specimens of *Myrmedonia collaris* and its larva taken in Wicken Fen with *M. loevinodis* in August, 1900.—The Rev. F. D. Morice exhibited a remarkable hermaphrodite of the bee *Podalirius* (= *Anthophora*) *retusus*, in which the male characters were confined to the left side of the head and genitalia, the right side of the thorax and the abdominal segments. The antennæ and hind (pollinigerous) legs were those of a female, and the genitalia half of each sex.—Dr. Chapman exhibited beetles of the genus Orina, some of them alive, and remarked on the fact that while some were viviparous others were oviparous, in the case of the former the larvæ being developed in the ovaries.—Mr. H. J. Elwes exhibited a collection of lepidoptera from Greece, taken this season in conjunction with Miss Fountaine in the Morea, and in the Parnassus region, including *Colias heldreichi*, *G. rhamni*, var. *farinosa*. and *Lycaena ottomanus*, with a var. of *L. semiargus*, probably a distinct species.—Mr. H. H. May exhibited a variety of *Strenia clathrata* not unlike *Syricthus alveolus* on the wing.—Mr. F. Enock exhibited a male bee *Stelis aterrima*, one of the bees parasitic in the nests of *Osmia fulviventris*, usually considered a rare insect.—Papers were communicated on "Descriptions of new species and a new genus of South American Eumolpidæ with remarks on some of the genera," by Mr. M. Jacoby, and on "Lepidoptera Heterocera from Northern China, Japan and Corea" (Part iv.), by Mr. J. H. Leech, &c.

### PARIS.

**Academy of Sciences**, October 15.—M. Maurice Lévy in the chair.—Preparation and properties of the carbides of neodidymium and praseodidymium, by M. Henri Moissan. The oxides of neo- and praseodidymium heated with carbon in the electric furnace give crystallised carbides of the formula $RC_2$, like the carbides of cerium and lanthanum. These carbides are decomposed by cold water, giving a mixture of acetylene, ethylene and paraffins, the first-named predominating. At 1200° the carbides are superficially attacked by ammonia, some nitride being formed.—Observations of the planet Eros made with the large equatorial of the Observatory of Bordeaux, by MM. G. Rayet and A. Féraud. The planet is of about the ninth magnitude, and leaves a clear trace upon the photographic plate.—On the general equation which gives the integral of Jacobi as a particular case, by M. Gruey.—Observations of the Borrelly-Brooks Comet, made with the Brunner equatorial at the Observatory of Lyons, by M. J. Guillaume.—The problem of stationary temperatures, by M. W. Stekloff.—On the explosive mixtures formed by air and by hydrocarbon vapours of the principal organic series, by M. J. Meunier.—On the elimination of the harmonics from alternating currents by the use of condensers, and on the interest of this elimination from the point of view of security of human life, by M. Georges Claude.—On the accessory reactions of electrolysis, by M. A. Brochet. In the electrolysis of sodium hypochlorite, the loss of hypochlorite in four hours is much greater than that calculated from the current used; and in the preparation of chlorate yields greater than those calculated are obtained. The author traces these anomalous results to the fact that the immediate neighbourhood of the anode is always acid, and hence the hypochlorous acid in that region is transformed spontaneously into chlorate without using electrical energy, even when the bulk of the liquid is alkaline.—On isopyrotritaric acid, a new pyrogenous product from tartaric acid, by M. L. J. Simon. The ferric salt of this acid, the isolation of which was described in an earlier note, is highly characteristic, possessing a deep violet colour in solution. Pyrotritaric acid and similarly constituted furfurane acids do not give this reaction, which is so sensitive that it may be used for the detection of ferric salts and also as an indicator in acidimetry.—On the morphology of the respiratory apparatus of the larva of *Bruchus ornatus*, by M. L. G. Seurat. The larva of *Bruchus ornatus* presents some peculiarities in the morphology of its respiratory apparatus which clearly distinguishes it from the Curculionidæ, the most important being the rounded form of the stigmata, the existence of a prothoracic ring completely uniting the lateral trunks, and of ten transversal latero-ventral anastomoses, of which three are thoracic.—The proteolytic ferment of seeds during germination, by M. V. Harlay. The proteolytic ferment in lentils during germination is analogous in its behaviour to the animal ferment trypsine.—On early tuberculisation in plants, by M. Noel Bernard.—On the Cretacian of the *massif* of Abou-Roach (Egypt), by M. R. Fourtau.—Fixation by porous bodies of clay in suspension in water, by M. J. Thoulet.

### NEW SOUTH WALES.

**Linnean Society**, June 27.—The President, the Hon. James Norton, in the chair.—Notes on some Australian and New Zealand parasitic Hymenoptera, with descriptions of new genera and species, by William H. Ashmead. Sixty-four species were represented in two collections brought together by Mr. W. W. Froggatt and Mr. A. Koebele, formerly of the U.S. Department of Agriculture. Of these forty-nine are described as new.—On the *Carenides* (Fam. *Carabidae*), Part iii., by Thomas G. Sloane. Nine species referable to the genera *Laccopterum*, *Carenum*, *Eutoma* and *Carenidium* are described as new, from Queensland, North-west, West and Central Australia. A synoptic table of the groups of species into which the genus *Carenum* may be subdivided is given, with notes thereon.—Descriptions of two new species of Diptera from Western Australia, by D. W. Coquillett. A species of *Phytomyza*, the larvæ of which mine the leaves of the beet, and one of *Myiophasia*, parasitic upon the Scarabeid *Anoplostethus opalinus*, Burm., are described. The second of these, founded upon male-specimens, may indeed be congeneric with *Neophasia picta*, Brauer and Bergenst., founded on a female specimen without antennæ from West Australia.—Descriptions of two new blind weevils from Western Australia and Tasmania, by Arthur M. Lea. Only two species of blind Coleoptera have hitherto been recorded from Australia, namely, *Halorhynchus caecus*, Woll., from West Australia, and *Illaphanus stephensi*, Macl., from New South Wales, both dwelling close to sea-beaches. An additional species of *Halorhynchus* from the "outer beach" at Geraldton, Western Australia, is described in the present paper, together with an insect for which a new genus is proposed, and of which the type-specimen was found in the nest of a small red ant near Hobart.—The double staining of spores and bacilli, by R. Greig Smith. An improvement upon Klein's method of double staining spores and bacilli is described. The spore-bearing material is distributed in normal saline in a small test-tube, an equal volume of carbol-fuchsin is added and the mixture placed in boiling water for fifteen minutes. A loopful is then withdrawn, spread over a coverglass, dried and fixed in a flame. The bacilli are decolorised in 1½ per cent. (by volume) of alcoholic hydrochloric acid, washed in water and counterstained in methylene blue. Even the most refractory spores are stained deep red, the bacilli blue.

July 25.—The President, the Hon. James Norton, in the chair.—Descriptions of new Australian Lepidoptera, by Oswald B. Lower. Forty species, referable to the *Bombycina*, *Geometrina*, *Pyralidina*, *Tortricina*, *Tineina* (*Œcophoridae*, *Gelechiadae*, *Elachistidae*, *Tineidae*), are treated of, thirty-seven being described as new.—On *Didymorchis*, a Rhabdocœle Turbellarian inhabiting the branchial cavities of New Zealand crayfishes, by Prof. William A Haswell, F.R.S. *Didymorchis* attracted notice during a search for allies of the *Temnocephaleae*, and is probably the nearest known relative of the group in question. The animal is about 1 mm. long and less than ⅓ mm. in greatest breadth; and as far as observed is practically an invariable companion of the crayfish *Paranephrops setosus*, though not occurring in large numbers. A remarkable feature is that cilia are developed only on a portion of the ventral surface of the body, and are entirely absent round the margin and on the dorsal surface. On the whole the animal seems to make a nearer approach to the *Vorticida* than to any of the other known groups.—Supplement to a monograph of the *Temnocephaleae*, by Prof. William A. Haswell, F.R.S. Three additional species of *Temnocephala* are described—*T. tasmanica*, allied to the much larger *T. quadricornis*, occurring in the branchial cavities, and occasionally on the external surface of *Astacopsis tasmanicus*; *T. aurantiaca*, found upon the lower surface of the abdomen of a Tasmanian Astacopsis, at present undetermined; and *T. coeca*, found upon the surface of the remarkable burrowing Isopod, *Phreatoicopsis terricola*, Spencer and Hall. The paper concludes with some remarks on certain points in the structure of the members of the family, mainly suggested by Monticelli's recent paper (*Bolletino della Soc. di Nat. in Napoli*, xii. 1898).—Observations on the Tertiary flora of Australia, with special reference to Ettingshausen's theory of the Tertiary cosmopolitan flora, Part i., by Henry Deane.—On the bacterial flora of the Sydney water supply, Part i., by R. Greig Smith. Thirty-two species of micro-organisms commonly occurring in Sydney water are described. These include six new species and four new subspecies.

## DIARY OF SOCIETIES.

*FRIDAY*, OCTOBER 26.

PHYSICAL SOCIETY, at 5.—Exhibition of Experiments illustrating certain Phenomena of Vision: Dr. Shelford Bidwell, F.R.S.—On the Concentration at the Electrode in a Solution, with special reference to the Liberation of Hydrogen by the Electrolysis of a Mixture of Copper Sulphate and Sulphuric Acid: Dr. J. S. Sand.—Electromotive Force and Osmotic Pressure; Dr. R. A. Lehfeldt.

*SATURDAY*, OCTOBER 27.

ESSEX FIELD CLUB, at 6.30.—Contributions to the Pleistocene Geology of the Thames Valley. The Grays Thurrock Area, Part I.: Martin A. C. Hinton and A. S. Kennard.

*THURSDAY*, NOVEMBER 1.

CHEMICAL SOCIETY, at 8.—Dehydrohomocamphoric Acid and its Oxidation Products: Arthur Lapworth.—Derivatives of Ethyl α-methyl-β-phenylcyanglutarate: W. Carter and W. Trevor Lawrence.—The Nitration of Acetamino-*o*-phenylacetate (diacetyl-*o*-aminophenol)—a Correction: R. Meldola, F.R.S., and Elkan Wechsler.—Rhamnazin and Rhamnetin: A. G. Perkin and J. R. Allison.—(1) Luteolin, Part III.; (2) Genistein, Part II.: A. G. Perkin and L. H. Horsfall.—Colouring Matter of the Flowers of *Delphinium consolida*: A. G. Perkin and E. J. Wilkinson.—The Action of Alkalis on the Nitro-compounds of the Paraffin Series, Part II.: Wyndham R. Dunstan, F.R.S., and Ernest Goulding.—Hexachlorides of Benzonitrile, Benzamide and Benzoic Acid: F. E. Matthews.—The Influence of Solvents on the Rotation of Optically-active Compounds, Part I.: T. S. Patterson.—Note on Gallinek's Amidomethylnaphthimidazole: R. Meldola, F.R.S., and F. H. Streatfeild.—The Action of Heat on Ethyl-Sulphuric Acid: W. Ramsay and G. Rudorf.—The Amount of Chlorine in Rain-water collected at Cirencester: Edward Kinch.

RÖNTGEN SOCIETY, at 8.—Presidential Address: Dr. J. B. Macintyre.
